Layering Methods for Inertial Fusion Targets

Neil B. Alexander, D.T. Goodin, A.S. Bozek, D.T. Frey, K. J. Boehm

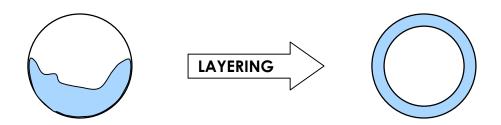

Inaugural IFE Science and Technology Strategic Planning Workshop:

Updates on Progress, Visions, and Near-Term Opportunities

> San Ramon, CA April 24-27, 2007

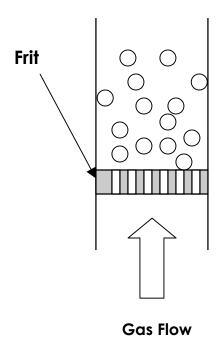

GA is developing Cryogenic Fluidized Beds for mass production of the fuel layering in IFE targets

Fluidized Bed

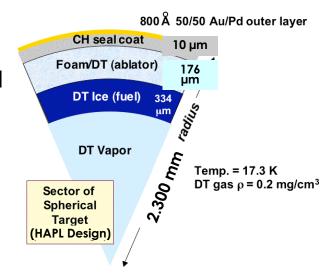

Mass production layering must:

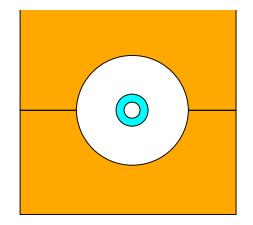

- Be reasonably fast
- Preserve other target properties
 - Surface roughness
- Be scalable to factory size

In DT fuel layering, fuel moves until inner surface is isothermal

- DT internal heating by betas allows sublimation until isothermal condition is reached
 - Thicker layers hotter
 - Layering time is many hours
- For D2 add heat to layer
 - Infrared (IR) light, or other
- Standard ICF method of holding target at center of isothermal cavity is inconvenient for IFE
 - Too many cavities,
 - Too much precision centering

Fluidized beds scale well for IFE power plant

and orders doctes to

Approximately 100' x 160' facility for 1000 MW(e) plant

Layering System Design Data

Loading Ports	
Permeation Cells in here	
	Layering beds
Injector	8 beds using 8 hrs to fill and cool, 13 hrs to layer, and 3 hrs to unload, Imply 65,000 targets/bed at 6 Hz shot rate.
Injector	

	Case A	Case B
Targets per bed	65,000	65,000
Diameter bed	200 mm	320 mm
Bed height, settled	112 mm	44 mm
Bed expansion	2	2
Bed height, operational	224 mm	88 mm
Operating temperature	18 to 19.7 K	18 to 19.6 K
Levitating fluid	Helium	Helium
Pressure of levitating fluid	380 torr	380 torr
Mass flow	55 gm/sec	140 gm/sec
Velocity of fluid	133 cm/sec	133 cm/sec
Pressure drop across bed	0.66 torr	0.26 torr
∆T across bed (1 Q _{DT} ; native betalayering)	0.134 K	0.054 K
Minumum fluidization velocity (U _{mf})	36 cm/sec	36 cm/sec
Ave. particle circulation time	0.70 sec	0.27 sec
Temperature change with time at inner surface of DT ice	<0.1 K	<0.003 K

Target motion in the cryogenic fluidized bed provides a time-averaged isothermal environment for uniform layers

- Particles (targets) levitated by a gas stream
- Beta heat from DT causes temperature gradient in bed (69 mK nominal conditions)
 - A de-layering influence
- Random circulation and rotation eliminates effects of temperature gradient

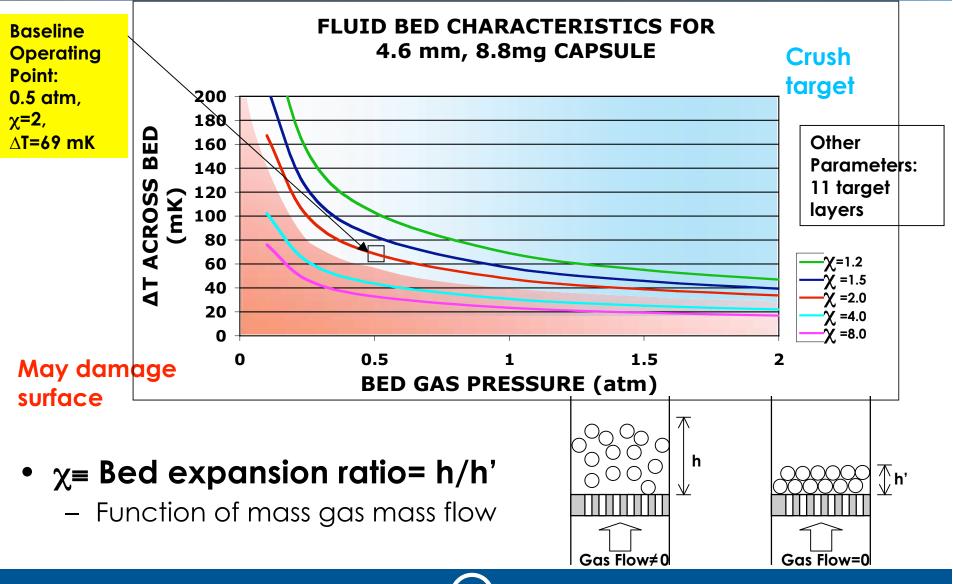

Before Hotter After When Betalayering Cooler Gas flow Here: 1 atm N_2 at RT Cryo: 0.5 atm He at 18K

Fluidized Bed with Bed Expansion =2

Neopentyl alcohol as room temperature

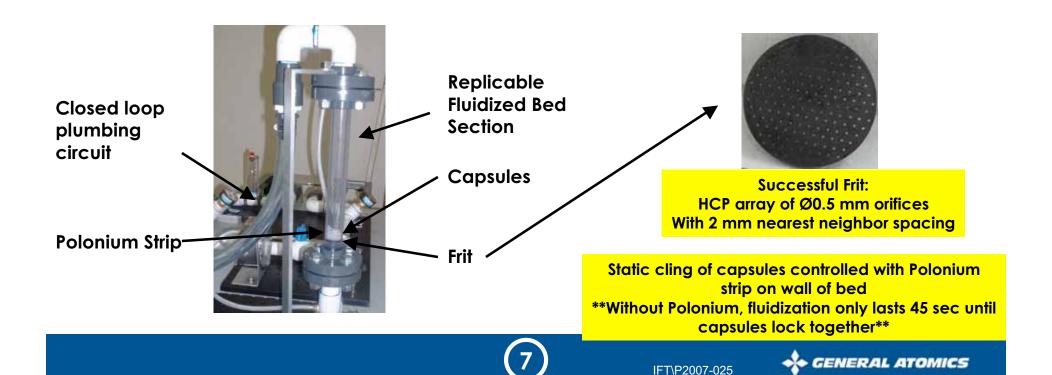

surrogate for DT

For uniform layers we want a small temperature gradient (ΔT) from bottom to top of bed

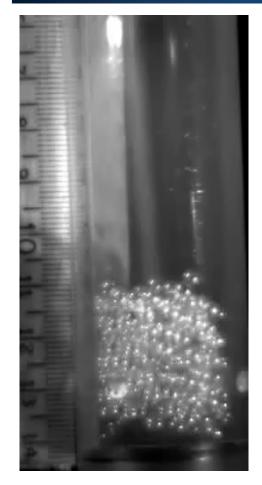

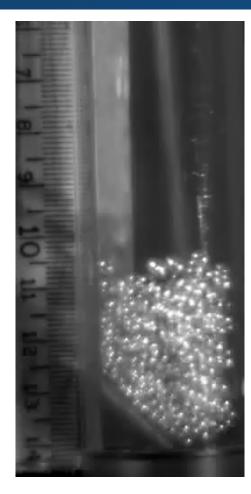

A fluidized bed test loop is being used to test bed configuration

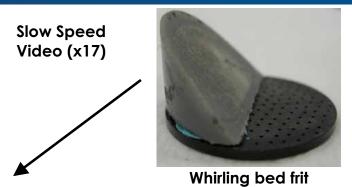

- Room temperature, closed loop using cryo-helium blower
- Cryo compatible frit design verified to produce good fluidization (no channeling)
- Alternate bed frits tested to change: capsule spinning, circulation in bed, and interactions

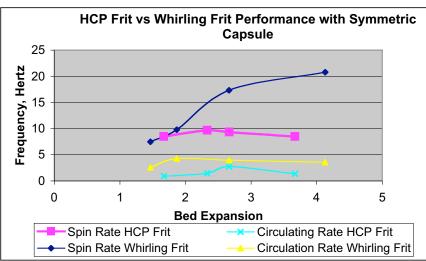

Whirling bed* enhances capsule spin and circulation within the bed

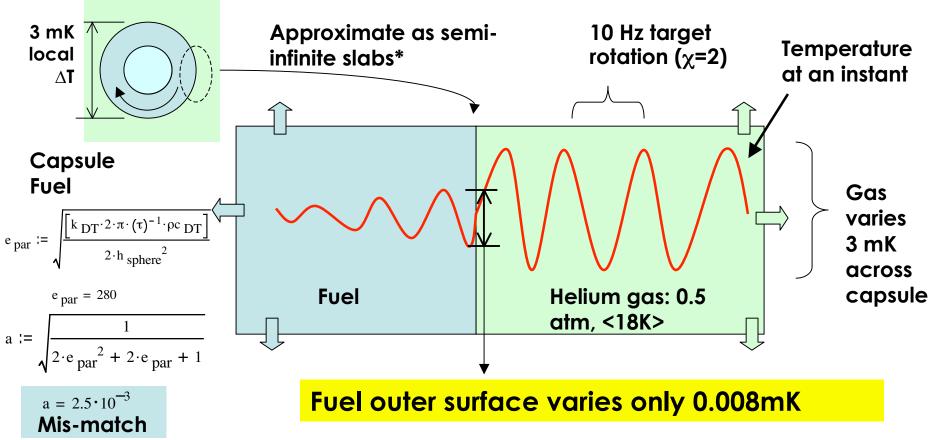

HCP frit

Whirling bed frit

• Nominal Bed Expansion (χ) of 2 has capsule spin rate = ~10 Hz

Temperature variations of helium gas are only slightly impressed onto fuel

- Differences in the thermal properties of fuel and helium gas lead to LARGE impedance mis-match at surface
 - Diffusivity, density, thermal conductivity, heat capacity, convection coefficient

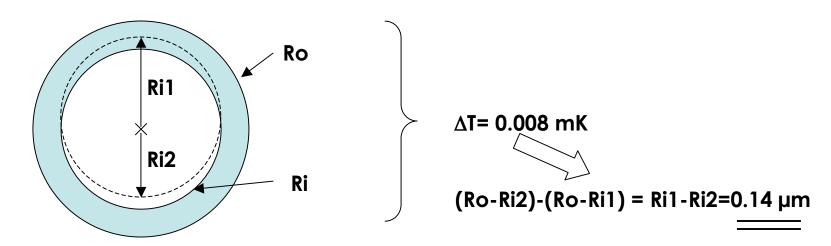

0.008mK temperature difference will yield 0.14 µm layer thickness difference to the beta-layer

- Apply dynamic ΔT to static model of fuel layer movement
- 1-D spherical model of beta-layering non-uniformities (from UR/LLE)

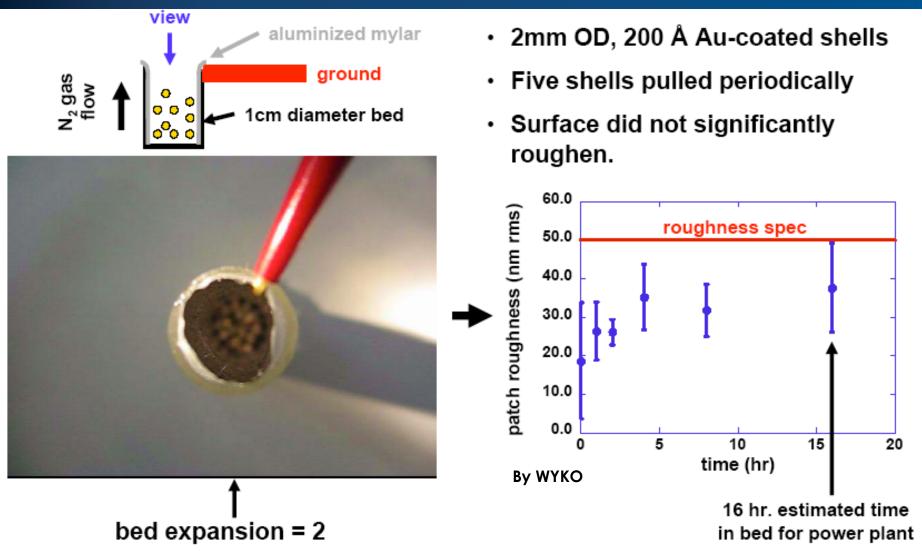

$$\Delta T = \frac{1}{6} \cdot \frac{\text{qdot}}{\text{k}_{L}} \left[\left[R_{0}^{2} - R_{i2}^{2} - 2 \cdot R_{i2}^{3} \cdot \left(\frac{1}{R_{i2}} - \frac{1}{R_{0}} \right) \right] - \left[R_{0}^{2} - R_{i1}^{2} - 2 \cdot R_{i1}^{3} \cdot \left(\frac{1}{R_{i1}} - \frac{1}{R_{0}} \right) \right] \right]$$

Ro = 2290
$$\mu$$
m (Ri1+Ri2)/2 = Ri=1780 μ m

0.14 µm is below HAPL layer specification of 5 µm rms all modes; 0.5 µm rms high modes.

Gold coating stays 'smooth' for a long time in the fluidized bed

Roughness ≈ Au layer thickness implies need to look for coating damage

Key MPLX scoping tests have been done

- Static cling of capsules is controlled
 - Polonium de-static strips

Circulation and spinning rates measured

Rates fast enough for uniform DT layer at χ=2 CIRCULATION
 SPIN

targets lock

together

move free

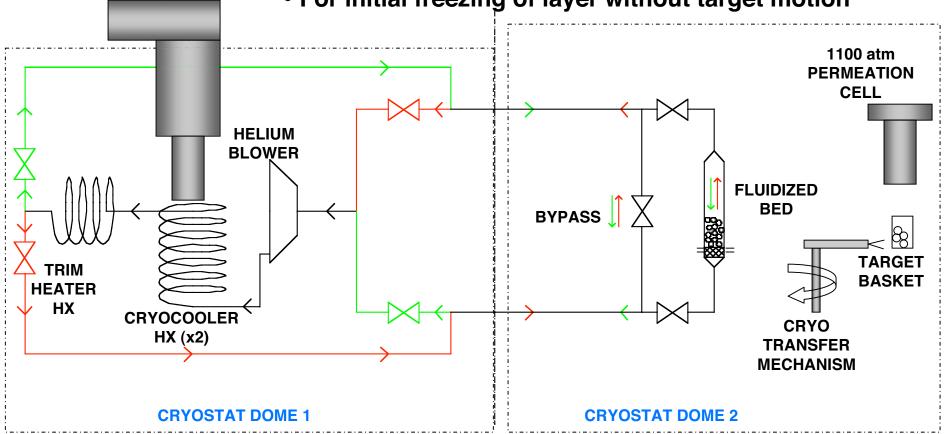

A cryogenic Mass Production Layering Experiment (MPLX) is being assembled

• For Deuterium Layers

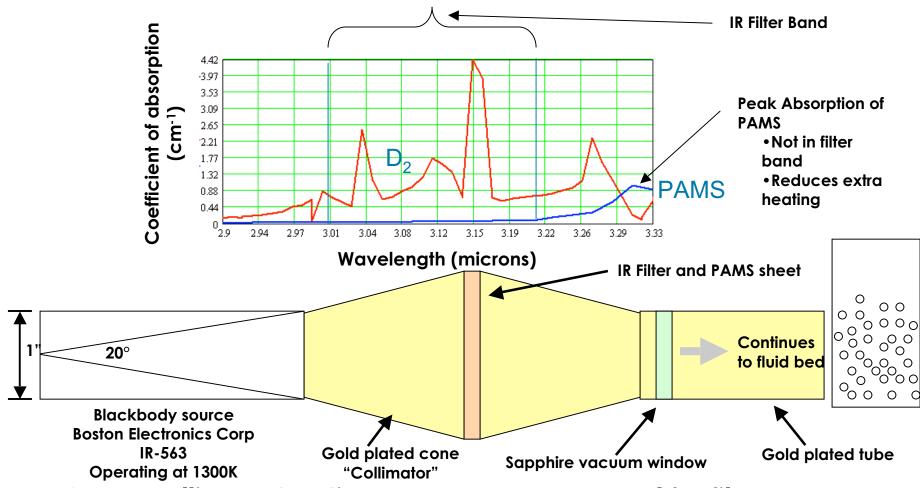

CRYOCOOLER (x2)

- Permeation filled targets
- All Cryogenic circulation loop
- Allows reversed flow in bed

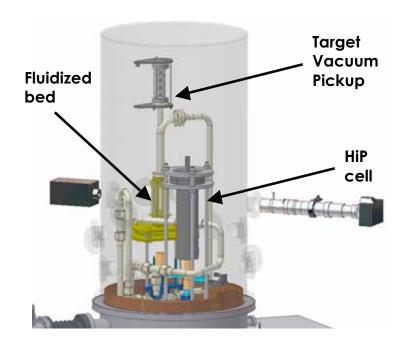

Design provides ~1Q_{DT} equivalent heating to 700 deuterium filled targets

Cone 'collimator' redirects rays to near normal for filter

Mass production layering experiment being brought online ...

Cryocoolers

Cryogenic circulator

Helium Compressors

> Hi-P cell (1100 bar)

~24 cm

Includes filling with HD (via permeation thru overcoats)

SUMMARY

- Fluid beds for layering scale nicely to power plant size
- Room temperature bed experiments show:
 - Static cling of targets solved
 - Spin rates measured should allow highly uniform layers to be formed in cryo-bed
 - Targets spin with offset mass
 - Initial roughness experiments show outer Au/Pd coating stays smooth enough
 - More experiments planned on layer damage
- Cryostat for layering deuterium in fluidized bed is in assembly

Appendix

Mass flow required for given bed expansion is determined from generalized correlation

Pick bed expansion χ

where is unexpanded bed void fraction

$$\varepsilon = \frac{\chi - 1 + \varepsilon_0}{\chi - 1 + 1}$$
 where is unexpand
for spheres ε_0 =0.4

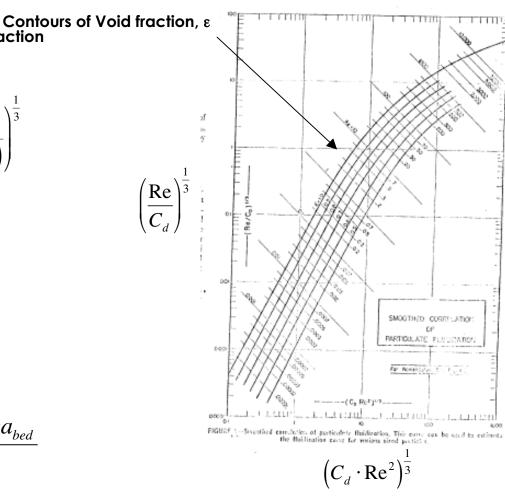

$$\left(C_d \cdot \text{Re}^2\right)^{\frac{1}{3}} = \left(\frac{4}{3}Ga\right)^{\frac{1}{3}} = d_p / \left(\frac{3\mu_{gas}^2}{4\rho_{gas}g(\rho_p - \rho_{gas})}\right)^{\frac{1}{3}}$$

These will determine $\left(\frac{Re}{C}\right)^{\frac{1}{3}}$

Superficial gas velocity will be

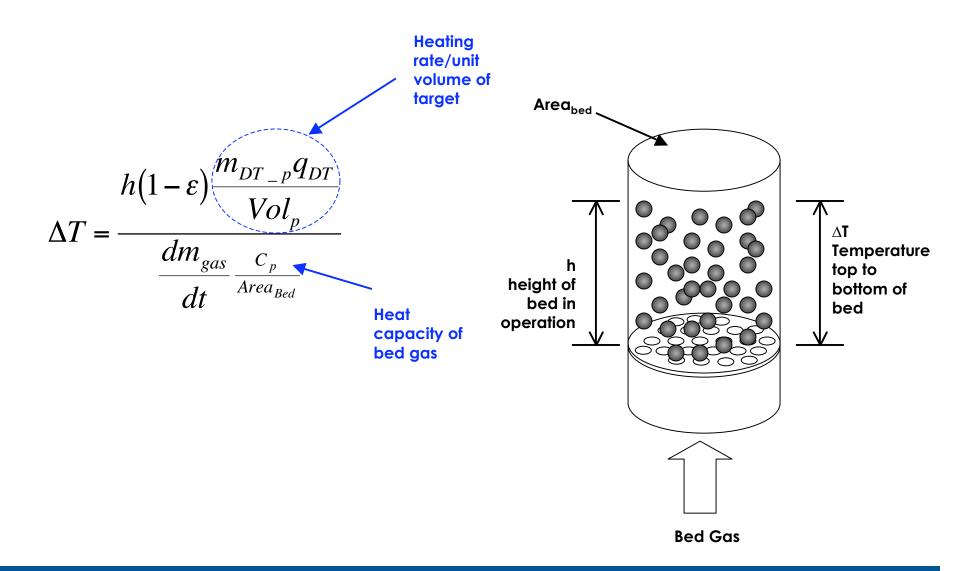

$$v_{gas} = \left(\frac{\text{Re}}{C_d}\right)^{\frac{1}{3}} \left(\frac{4\mu_{gas}(\rho_p - \rho_{gas})g}{3\rho_{gas}^2}\right)^{\frac{1}{3}}$$

Mass flow
$$\frac{dm_{gas}}{dt} = \frac{M_{gas}Pv_{gas}Area_{bed}}{RT}$$

F.A. Zenz, Fluid Bed Reactors Design, Scaleup, Problem Areas, AIChe Today Series, American Institute of Chemical Engineers, 1974, New York, pg 2-3

Beta or other heating warms bed from bottom to top

The circulation time of a target in the bed can be estimated

The circulation time of a particle in a fluidized bed is given by Rowe as

$$t_{p} = \frac{H_{mf}}{0.6(U - U_{mf})\left[1 - \left(\frac{U - U_{mf}}{U_{b}}\right)\right]}$$

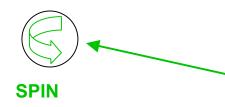

Where

 \mathbf{H}_{mf} is the height at minimum fluidization (~settled height), U is the superficial velocity of the gas, \mathbf{U}_{mf} is the minimum velocity for fluidization, U_b is the bubble (a void in particles) velocity.

Yates combines the Ergun equation with the empirical results of Wen and Yu for minimum fluidization voidage to obtain

$$U_{mf} = \frac{\mu}{d_p \rho_g} \left\{ 33.7^2 + 0.0408 \frac{d_p \rho_g (\rho_p - \rho_g) g}{\mu^2} \right\}^{1/2} - 33.7$$
 Where μ is the viscosity, d_p is the particle diameter, ρ_g is the density of the gas, ρ_p is the density of the particle,

All inputs required come from bed design except bubble velocity, U_b

g is the acceleration of gravity.

CIRCULATION

Expressions exist for bubble velocity

Davidson and Harrison give the average bubble velocity as

$$\overline{U}_b = (U - U_{mf}) + 0.711(gd_b)^{1/2}$$

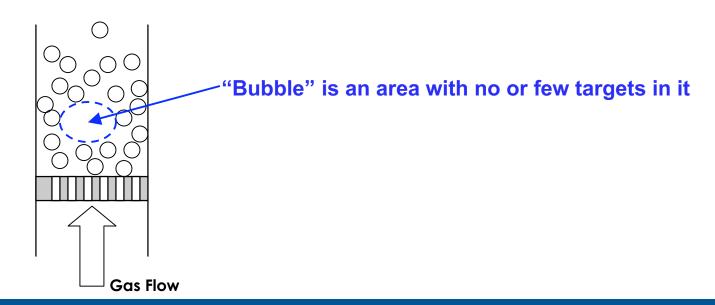

Where

d_b is the bubble diameter.

Substitute into expression for t_p

Take integral average over all possible bubble diameters

0 to (bed diameter or bed height; whichever is smaller)

Circulation time of a target in the bed can be short

Take an intregral average of t_p for all possible d_p's

0 to bed diameter

	HAPL	Initial MPLX	Room
	Target	target	Temperature Experiment
Diameter (mm)	4.6	4.0	4.0
Mass (mg)	8.4	5.3	1.9
Fuel	DT	D2 (with	Empty

2 mg offset mass injected into capsule
 Similar to a starting condensed capsule

Faster layering is accomplished by adding heat to DT layer

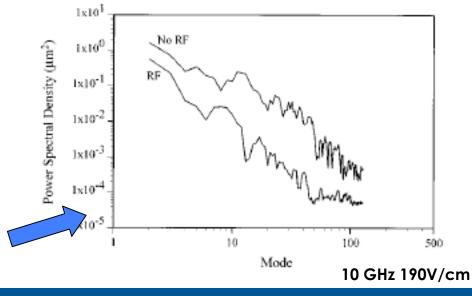

- Layering time constant is
 - $-\tau = H_{sublimation}/(Q_{DT} + Q_{added})$
 - Q_{DT} is heat of tritium beta's
 - Beta-layering has τ = 26 min = **1560 sec**
 - $Q_{added} = 0$

Adding heat flux through layer smoothes

layer*†

Plasma discharge layering has potential to quickly make smooth layers at low temperatures

- Target random motion in Fluidized Bed should overcome non-uniformities in previous plasma layering experiments
 - Target held in fixed position with its fill tube*
- 10K is field discharge minimum at 2.45 GHz for D2 IFE target
- Norimatsu had layering redistribution time of 1.3 min
 - Native beta-layering this is 26 min

Coax Microwave feed

Implies layering plant could be even smaller.

•We propose adding to fluidized bed to plasma discharge layering method of Norimatsu (ILE)*

Phenomena, April 24-28, 1995,

Osaka, Japan

Helium Flow

Gold layer on capsule causes some field loss

- 300 Å is very thin
- Skin depth of gold at 2.45GHz
 - 1.6 micron at room temperature
 - 740 Å at 8K
 - There is some variability in low temperature resistivity data
- Field loss is only 33% into capsule interior
 - (1-exp(-300A/740A))
- If needed use:
 - Lower frequency
 - Add Palladium to raise lower temperature electrical conductivity

Plasma layering may impose tolerances on the capsule uniformity

- Polymers will absorb some heat from microwaves
- Heat in capsule will impose some of the non-uniformity of the capsule onto the DT
- Effect is to be analyzed

Progress on Surface Roughening of W/SIC Exposed to IFE

Michael Andersen and Nasr M. Ghoniem

University of California Los Angeles (UCLA)

Goal: Predict material life from crack nucleation formation by modeling surface roughening

Problem Statement

Grooving patterns can appear in long rows, but notice that a crosshatch formation ends the valleys from continuing indefinitely.

Experimental data show that the surface of tungsten exposed to laser, ion, and X-ray irradiation undergoes substantial roughening with a variety of patterns and features. Control of surface conditions is essential to the design of these systems, since it can lead to crack formation, adverse effects on heat absorption because of emissivity changes, and eventual failure. For this reason, a quantification of the surface must be studied and utilized to determine surface integrity.

 $F(x) = F(E) * \frac{dE}{}$

 $G(x) = \widetilde{C}(x) * Hz$

 $\widetilde{C}(x) = C(x) * \Omega = F(x) * \Omega$

Review of Earlier Work

First an energy spectrum is determined from a given target, which can then be used to find the atomistic characteristics of each pulse using a program called the Stopping and Range of lons in Matter (SRIM). SRIM determines on average where an ion with a given energy ends up. Also with the energies from each ion we can find flight time and ultimately time of interaction on the material. With this information we can use a modeling program to determine temperature of the material over a given time.

Spectrum provided by ARIES, UCSD

In order to study the evolution of the surface profile, a description of the chemical potential and how it
applies to material transport needs to be established. The chemical potential, μ, can be described as

$$\mu = \mu^* + \gamma \Omega \kappa + \Omega \omega$$

Where μ^* is the chemical potential of a flat surface bounding the solid with bulk stress σ^o , γ is the surface energy, Ω is the atomic volume, κ is the surface curvature, and ω is the strain energy. The strain energy is found from Hooke's law as:

$$\begin{split} \omega &= \frac{1}{2} \varepsilon_{ij} \sigma_{ij} \\ \omega_{b} &= \frac{(1 - v^2)}{E} \sigma^{\infty} \end{split}$$
 Siress on the surface turns out to be one of the tricky parts of the problem. Here we will use BEM or

Where ω_b is the bulk strain energy and ω_s is the surface strain energy for plane strain. The surface material transport is determined by the Nemst-Einstein relation of the diffusion flux proportional to the surface gradient of the chemical potential given as

$$J = -\frac{D_s}{kT} \frac{\partial \mu}{\partial s}$$

Where D_a is the surface diffusivity, k is the Boltzmann's constant, T is the absolute temperature and the derivative with respect to the arc length, s, is evaluated along the surface. The normal velocity of the surface V. is then proportional to the divergence of J:

$$V_n = -\frac{D_s \Omega v_s}{kT} \frac{\partial^2 \mu}{\partial s^2}$$

Where v_s is the number of atoms per unit area of the material in the plane normal to the flux direction. This can be extended to the surface profile h(x,t) as

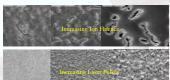

Here we can see a roughening zone created by the biaxial stress state. With the normal velocity found we can determine the movement on the surface

Roughening Mechanisms

There are several test facilities running experiments on the nature of surface reactions to laser, ion, and x-ray. These included the Dragonfire facility at UCSD, XAPPER at Lawrence Livermore, and the RHEPP at Sandia. The hope is to create a model that agrees with these experiments.

Surface Stresses can be relatively straight forward to calculate when the surface is flat, but as it begins to roughen the problem becomes out of the scope of simple equations and needs a

modeling approach. Above, we can see a straight forward approach to finding surface

stresses from a laser energy source. Hector and Hetnarski JAM '96

Effect of increasing ion fluence and increasing number of pulses. Ion work done by T. Renk, SNL presented for HAPL. Laser work done by F. Najmabadi and J. Pulsifier at UCSD and again presented for HAPL

Roughness from the

incident time. (J.F

By knowing the spectrum of ions with respect to energy and finding the dispersion of ions with respect to distance

concentration can be found analytically. This allows quick calculations for new target spectrums—all that is

needed is the percentage of

and at what energies

- (ME, 980)

peak to valley. (Renk SNL)

Roughness on the order of 10's order of 10's

It should be noted that BEM has one flaw. Stresses inside the boundary can be found, but they contain a 1/r parameter that leads to a singularity when you approach the surface. A more accurate way is used where the stresses on the surface are calculated by differentiating the surface displacements. This is how the graph below is so smooth without fluctuations.

Boundary Element Method (BEM)

A key component of this problem is determining the stress along the surface as the morphology changes. This was first approximated with general elasticity, but needed to be more clearly defined around the changes in the surface. As the valleys deepen toward a crack, the stress increases dramatically as does the need for more definition with increasing curvature. A boundary element method is used based upon discretizing only the surface instead of the whole volume. This makes it much easier to code and follow changing surfaces. The defining equation for this method is shown below.

$$\int \overline{T}_{ij}(x,\xi)u_j(\xi)dS(x)$$

T is the elastic Green's function that satisfies the periodic boundary conditions and u is the displacement field. The key to this method is that it is only over the surface and does not need information from inside the material. Stresses can be found inside the material nonetheless.

There are two BEM codes used for this work. The first is 2D with 3 nodes/element and the second is 3D with 8 nodes/element. Input for the codes is same: node coordinates, nodal connectivity to the elements, traction and surface displacements

Stress at the valley of the roughened zone

s shown to increase quite dramatically as

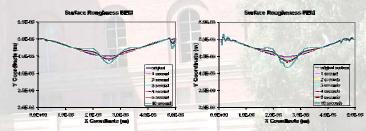

This is as expected as local stress around

valley would eventually approach that of a

the amplitude over wavelength increases

02

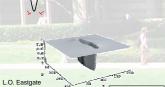

As a validation to how well the BEM works, it is compared to a FEM analysis (ANSYS). As can be seen the results are very agreeable. The BEM has the advantage of being programmable with automatic surface changes without the recurring user interface needed with FEM.

Status Report

2D needs to be finished off with a few advancements including transient inclusion, long-time runs, effects of plasticity, and the possible addition of defects around the crack tip. Previous research has stopped once the roughness begins to form. The curvature and stress approach extreme values and calculations become too excessive to continue the growth. By including plasticity and consequent dislocations and blunting, we can control these stresses and continue the nucleation.

The work eventually needs to be extended to 3D where the derivatives over the surface becomes slightly more complicated as the Laplace-Beltrami operator must be used to find the derivatives of the chemical potential. Key to this work will be the BEM because as the surface changes, the stress calculation will become more and more difficult. Only needing to mesh the surface will make this possible.

Shown here are dislocations coming from the crack tip. This keeps the stress from

UCLA

The behavior of liner surfaces where the surfaces with the surface

Abstract

At the energy density required for Magnetized Target Fusion (MTF), the liner, or in general any pusher material that compresses the target, is subjected to high pressures and intense Ohmic heating, as well as radiation and possibly particle bombardment from the target plasma. A series of experiments are underway to study the response of aluminum to the megabar pressures and MG fields anticipated in MTF experiments. To allow good diagnostic access, a simple geometry has been adopted. The MG fields are generated at the surface of cylindrical metal conductors that carry current. The configuration is therefore a classic z pinch in which the metal to be studied is the object being pinched. At MG fields the pressure is so high that material strength can mostly be ignored, and the configuration is unstable to the classic MHD modes. Generally parameters are chosen so that the growth time for instability is longer than the time to reach peak field, and in addition the skin depth of the field is chosen to be small compared to the conductor radius. This skin depth regime is distinct from that of exploding wires in which the skin depth is made larger than the conductor radius.

*Work supported by DOE-OFES grants DE-FG02-04ER54752 and DE-FG02-06ER54892.

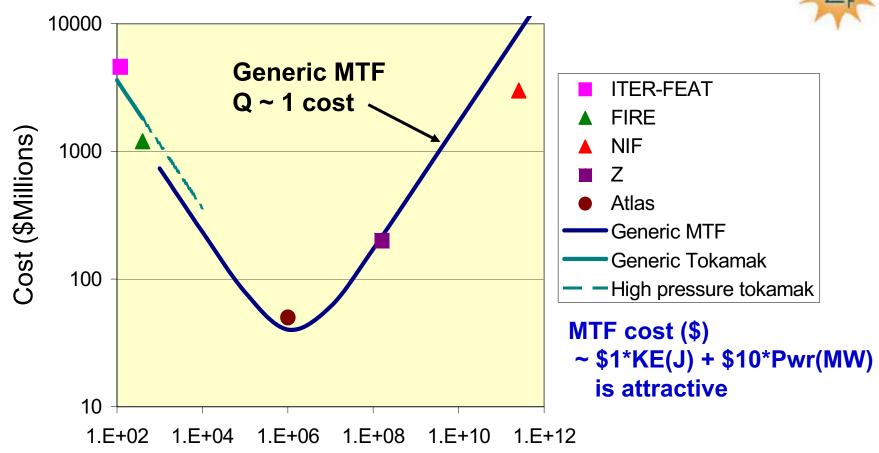

Test modeling with experiment: 1 MA in 100 ns through 1-mm-diameter Al wire

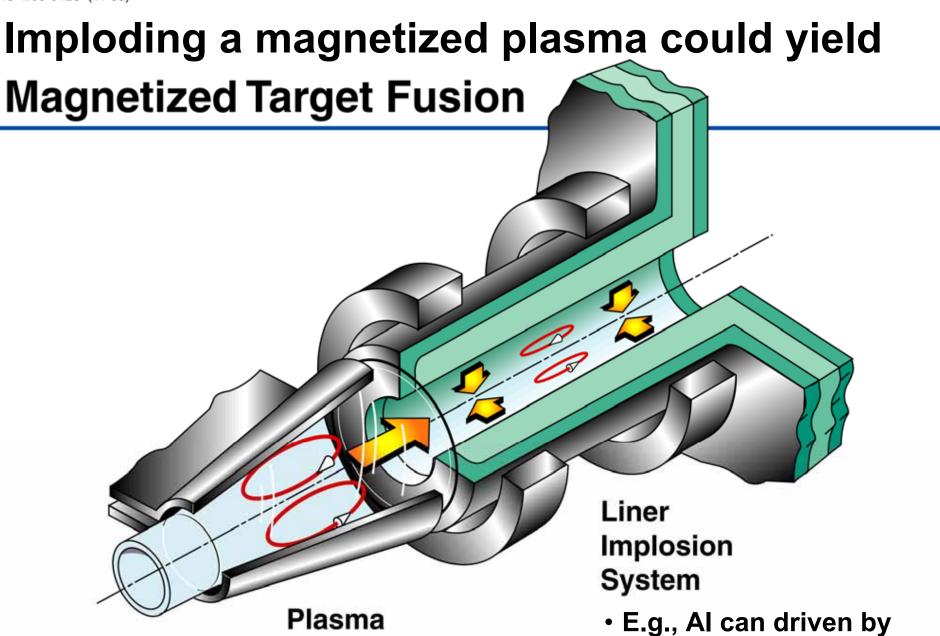

- 1. What is Magnetized Target Fusion (MTF)?
- 2. When can a z-pinch be used to study liner physics?
 - When current skin depth < cylinder radius i.e., when δ/a < 1, so *not* a wire explosion
 - ➤ When m=0 & m=1 instability growth is limited
 - When plasma formation by electric field is limited
- 3. Zebra experiment: 1 MA in 100 ns through 1-mm-diameter Al wire: $\delta/a \sim 0.05$
- 4. Modeling with MHRDR is being compared with experimental data

Magnetized Target Fusion (MTF) seeks minimum-cost trade-off between input energy & power

Pressure (atmospheres)

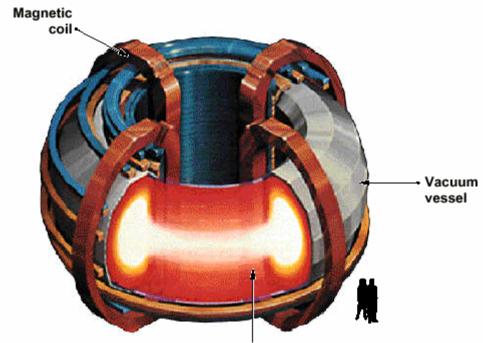

Injector

 $I > 1 MA, B_{\theta} \sim 100 T$

Magnetic and inertial fusion are separated by 10¹¹ in fuel density & confinement time

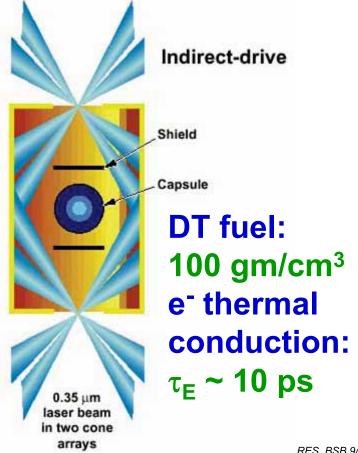

Gain=1 (Lawson): $n\tau_E \ge 12 \text{ kT/} < \sigma v > E_f$ $\sim 10^{14} \text{ cm}^{-3} \text{s} \sim 10^{-9} \text{ s g/cm}^3$

DT fuel: 10⁻⁹ gm/cm³

 $\mathbf{j} \times \mathbf{B} = \nabla \mathbf{p} : \tau_{\mathbf{F}} \sim \mathbf{1} \mathbf{s}$

Low-cost electric pulsed power can apply plenty of pressure, energy, & power

- Superconducting magnets (constant)
 - B < 15 Tesla
 - p < $\beta B^2/2\mu_0$ ~ 100 atmospheres
- Laser compression (pulsed)
 p ~ 10¹¹ atmospheres

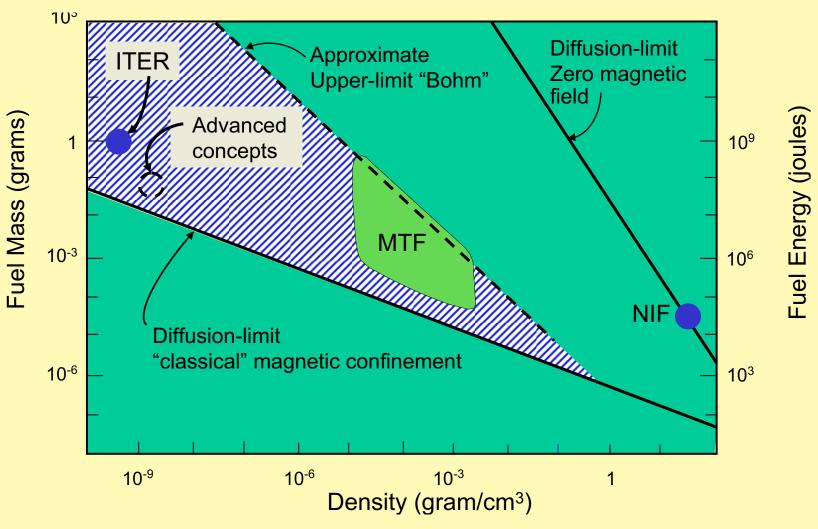

The input energy & power required for fusion are set by the fuel pressure & β

T = 10 keV; p, β
$$\rightarrow$$
 n = p/(2kT)
 $\tau_E = [n\tau_E] / n$
B = $(2nkT/β)^{1/2}$

- Thermal diffusivity $\chi = f(n,T,B)$ e.g., $\chi_{Bohm} = kT/(16eB) \sim 1 \text{ m}^2/\text{s}$
- \rightarrow R = $(\chi \tau_E)^{1/2}$, Volume = const*R³ $\propto \tau_E^{11/2} \propto p^{-11/2}$
- Energy = 3nkT*Volume $\propto p^{-1/2}$ Power = Energy/ $\tau_E \propto p^{1/2}$

MTF regime is intermediate between MFE and ICF

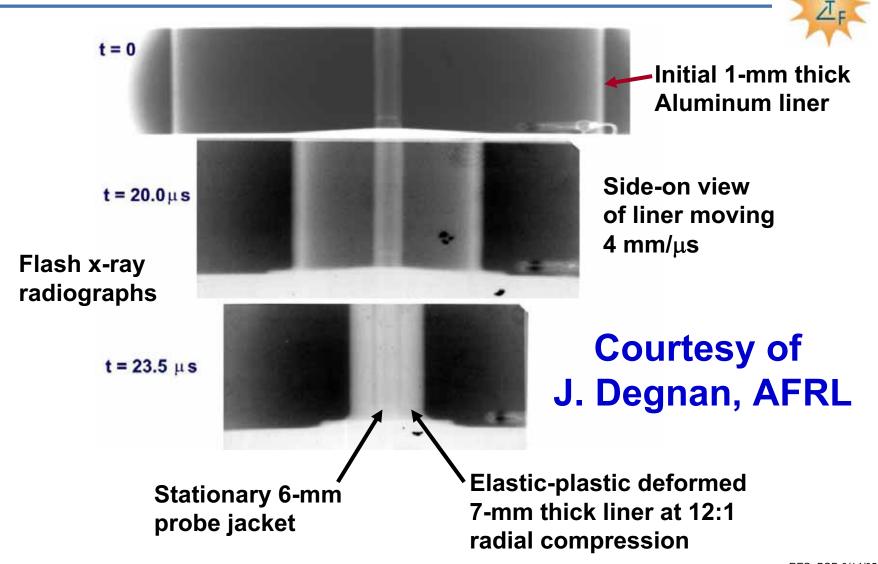

DT Fuel Mass heated to 10 keV

Principal MTF issues

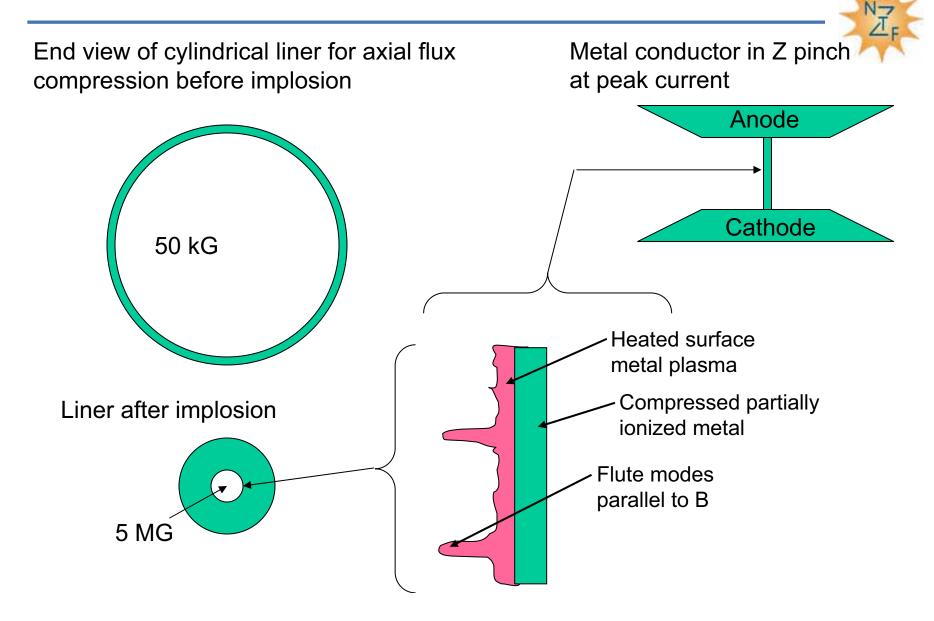

- Plasma target issues
 - -- formation method?
 - -- stability?
 - -- energy confinement?
- Liner physics issues
 - -- what determines maximum B?
 - -- what about RT during liner deceleration?
 - -- how much high-Z mixing with DT fuel?
- Can economical and practical MTF be developed?

Radiographs of liner implosion demonstrate good liner performance

Study liner physics with a z-pinch when surface conditions are similar

Regimes depend upon ratio δ /a = skin depth / radius

This is discussed in many places, eg., Knoepfel's book

Magnetic field diffusivity $\chi_B = \eta/\mu_0$ $\delta = \text{sqrt} (\tau \chi_B)$

Define V_A with surface B field and internal metal density

Consider Ohmic heating of ionized metal with some <Z>

 $\delta /a >> 1$

 $kT \sim M_i V_A^2 (\delta/a)^2$

Plasma pressure >> magnetic pressure

Regime of exploding wires

 δ /a << 1

 $kT \sim M_i V_A^2$

Plasma pressure ~ magnetic pressure

Regime of liner surfaces

B is limited by stability

Assuming rod with density ρ will disrupt after time τ

$$\tau \sim \frac{R}{V_A} = f_s \frac{R}{B} (\mu_0 \rho)^{1/2}$$

where f_s is a semi-empirical number

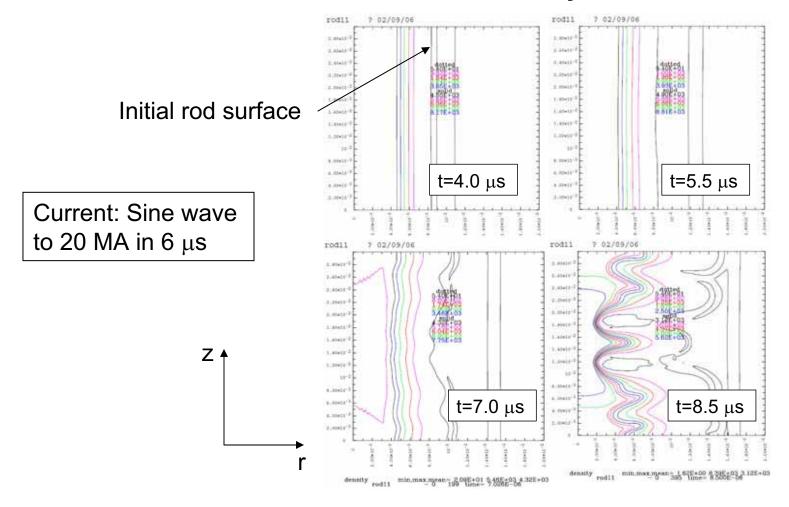

then rod radius should be chosen based on current I and rise-time au

$$R = \left(\frac{\mu_o I \tau}{2\pi f_s}\right)^{1/2} \frac{1}{(\mu_o \rho)^{1/4}}$$
thus
$$B = \left(\frac{\mu_o f_s I}{2\pi \tau}\right)^{1/2} (\mu_o \rho)^{1/4}$$

2D simulation suggests stability $f_s \sim 6$

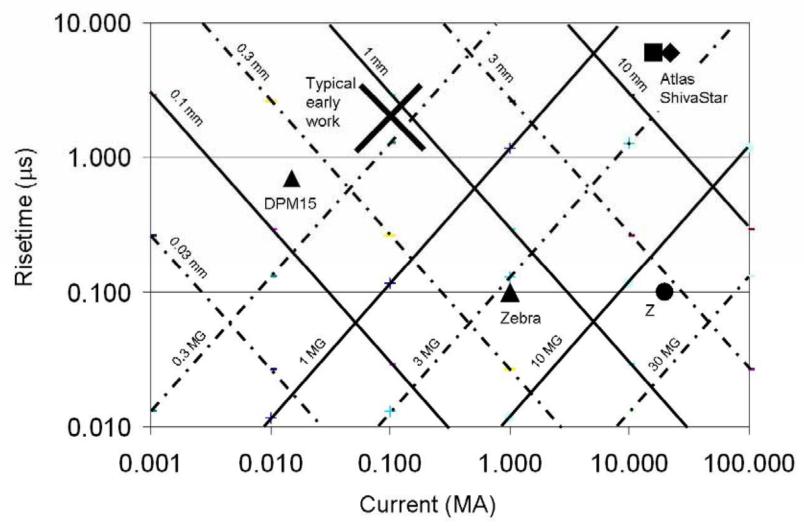

Metal density contours

Minimum rod radius & maximum B are constrained by stability for given current & rise time

Simulation of B diffusion

- •Surface plasma results from Ohmic heating
- •Correct numerical modeling depends upon:
- -- careful zoning,
- -- material properties(significant uncertainty)
- -- radiation transport plus electron thermal conduction
- •Plasma forms at surface when $B \cong 3 \text{ MG}$
- •For B < 10 MG, small fraction of current flows in the surface plasma

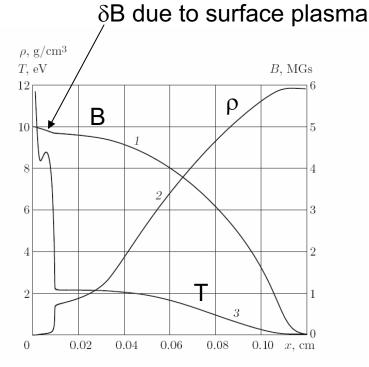

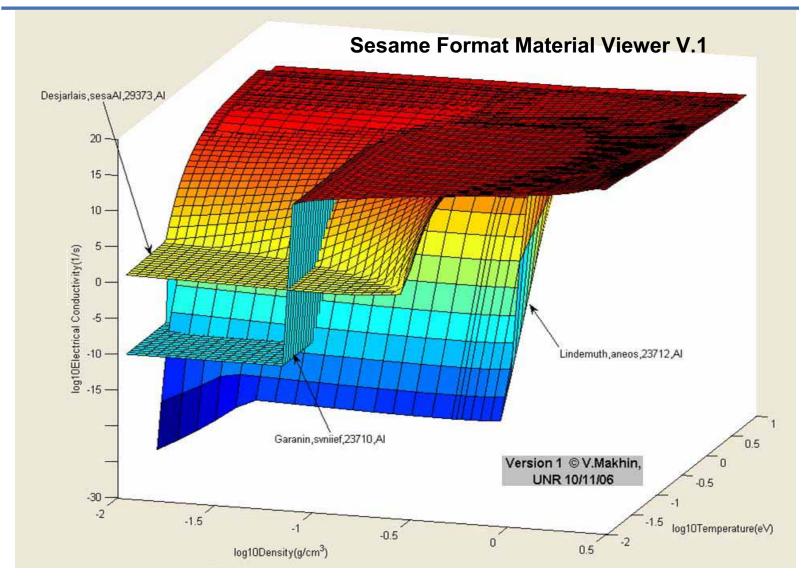

Fig. 3. Spatial curves of the magnetic field B(x) (1), material density $\rho(x)$ (2), and material temperature T(x) (3) calculated for an open system with a linearly increasing magnetic field at the boundary for $dB_0/dt = 5 \text{ MGs}/\mu\text{sec}$ at $t = 1 \mu\text{sec}$.

Electrical conductivity varies by table

MHRDR rad-MHD modeling finds plasma formation on surface

Density, B, and temperature vs. radius, at 170 ns (I = 935 kA)

Conclusion

- ✓ MTF is an exciting possibility for economical fusion
- ✓ MTF liner physics is being cost-effectively studied by using a z-pinch configuration
- ✓ The effect of multi-MG field with δ /a < 1 is being studied with experiments on the 1-MA Zebra z-pinch
- ✓ Hourglass-shaped loads emit most uniform light
 => may compare best with 1-D modeling
- ✓ Comparisons with rad-MHD models show promise

Diagnostics for ion beam driven targets and warm dense matter experiments

Frank B

IFE Science and Technology Strategic Planning Workshop April 24-27, 2007

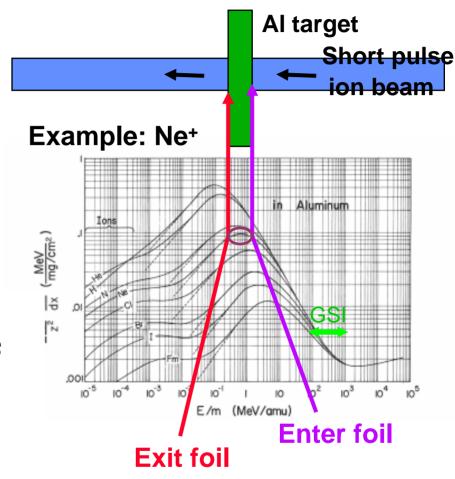

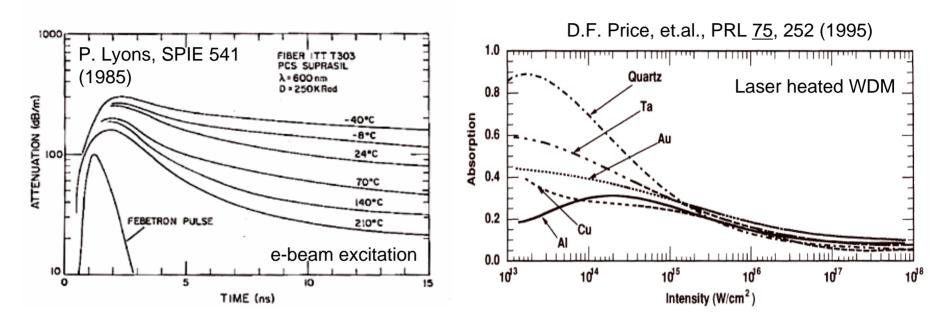

Ion beams provide an excellent tool to generate homogeneous, volumetric warm density matter.

- Warm dense matter (WDM)
 - T ~ 0.1 to 10 eV
 - $-\rho \sim 0.01$ -1 * solid density
- Techniques for generating WDM
 - High power lasers
 - Shock waves
 - Pulsed power (e.g. exploding wire)
 - Intense ion beams
- Some advantages of intense ion beams
 - Volumetric heating: uniform physical conditions
 - Any target material
 - High rep. rate
 - Benign environment

L. Grisham, Phys. Plasmas 11 (2004) 5727.

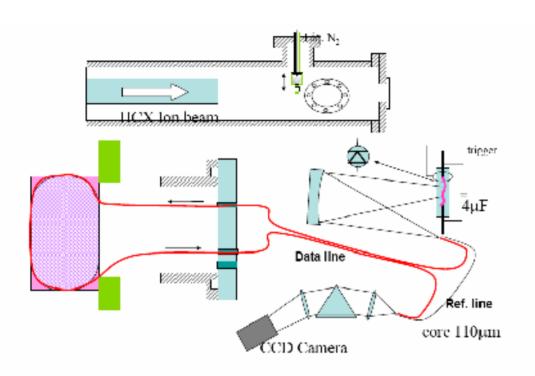

First experiment: Check WDM atomic models using transient darkening of quartz at low temperature.

In quartz, electrons excited from 2s, 2p (ground state) to 3s leave holes in ground state to absorb photons in both cases. Measure decay rate of excited electrons by studying decay of absorption and emission rates.

Significance: interpret WDM data, possible temperature measurement, fast switching of optical properties

Initial transient darkening experiments in quartz fiber (with H. Yoneda, U. of Electro-communications, Tokyo).

Optical transmission experiment: look for difference in fiber transmission with and without beam.

Modeling of effect of ion beam on optical fiber transmission is going on.

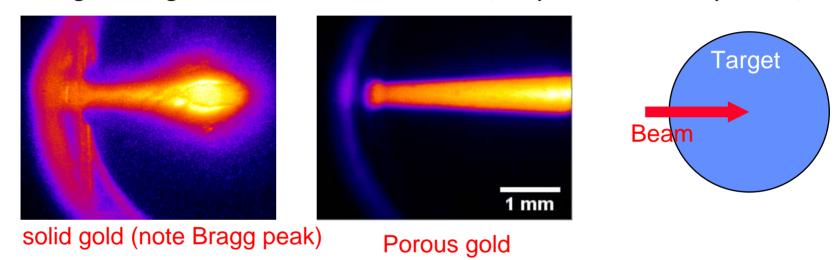

Porous target experiment Dec. 2006 at GSI HHT target station (with GSI Plasma Physics group; IPCP Chernogolovka; ITEP Moscow).

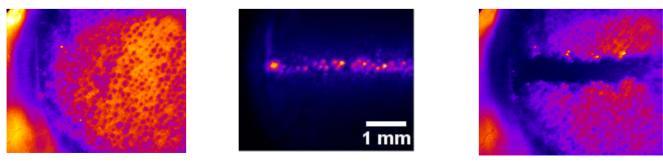

- ·Replace target foil with porous material.
- •Study effect of pore size on target behavior using existing diagnostics.
- •Sample targets: LLNL (Au, 50 nm), Mitsubishi (Cu, 50 micron).

Data analysis from GSI experiments is underway.

 Gold targets heated to about 6000 K (T-boil = 2435 K). Solid and porous gold targets show similar behavior (temp, 1.4 km/s expansion).

 Copper targets heated to about 3000 K (T-boil = 3200 K). Porous copper broke up into droplets.

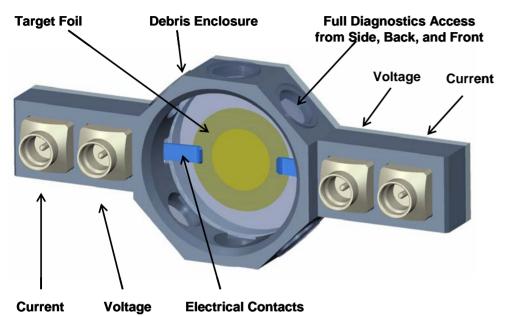

Porous copper – before, during, after beam pulse

PROTOTYPE TARGET MODULE

(Size: 5.66 cm wide, 2.29 cm high)

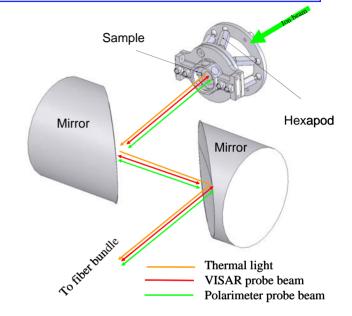

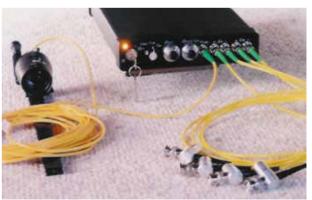

TARGET CHAMBER UNDER CONSTRUCTION

Target diagnostics - 1

- Fast optical pyrometer
 - fast response (<1 ns) and improved sensitivity at lower threshold temperature
 - Temperature accuracy 5% for T>1000 K
 - Position resolution about 400 micron
 - Parts are being ordered to be assembled in FY07
- Fiber-coupled VISAR system completed bench test
 - Martin Froescher & Associates
 - ps resolution
 - 1% accuracy
- Hamamatsu visible streak camera with image intensifier
 - ps resolution
 - arrived Feb. 2007

Target diagnostics - 2

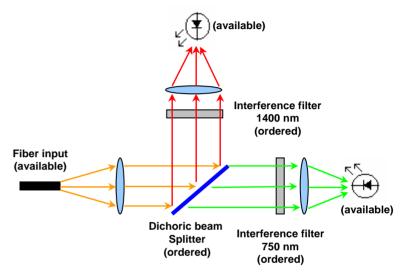

- Princeton Instruments PI-MAX cameras (2 on hand) for single frame images of target – 16 bits, 512 x 512, 1 ns and 10 ns resolution.
- Electrical conductivity
 - initial test to be based on electrical transmission line circuit
 - conductivity may switch between insulator ←→ conductor
- Diagnostics to be developed include
 - Laser optical transmission/reflection/polarimetry
 - X-ray diagnostics

Two-wavelength pyrometer (classical)

-750 nm and 1400 nm channels

- -Fixed, high gain, broad band photo-receivers (conversion gain up to 2.5 x 103 V/W)
- -180 ps temporal resolution
- -High sensitivity, can measure down to 1000 K
- -Ideal for initial experiments
- -Can be used for target "preheat" measurements

Working scheme:

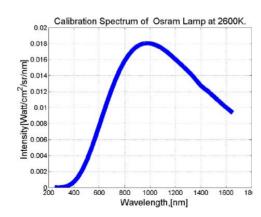

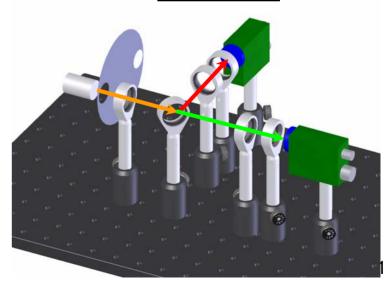

CAD model:

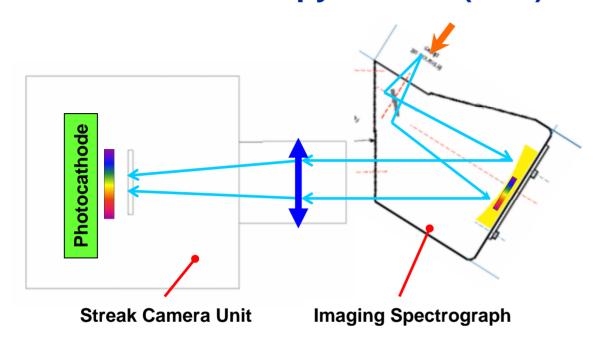

Calibration lamp: Osram W 17/G

Tungsten ribbon

Streak pyrometer (new)

Imaging spectrograph HORIBA, CP-140 400 nm -900 nm (on order)

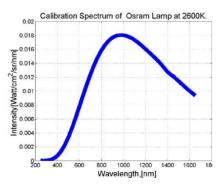

Hamamatsu streak, C7700 (available)

Radiance calibration with tungsten strip lamp (ordering)

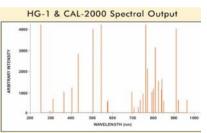

Calibration lamp: Osram W 17/G

Tungsten ribbon

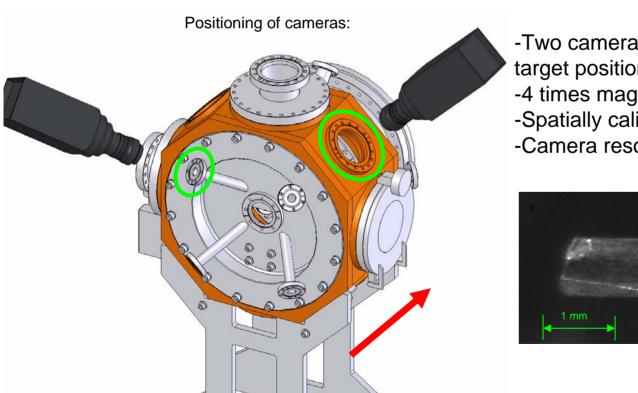

Wavelength calibration with Mercury-Argon Calibration lamp (available)

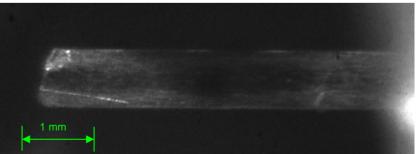

Cameras Tele-converter (optional) f=400 mm Any distance CCD Precise coated doublet achromat for visible light Tele-zoom objective, Elicar, Free of aspherical and coma aberrations. f=1600 mm (ordering)

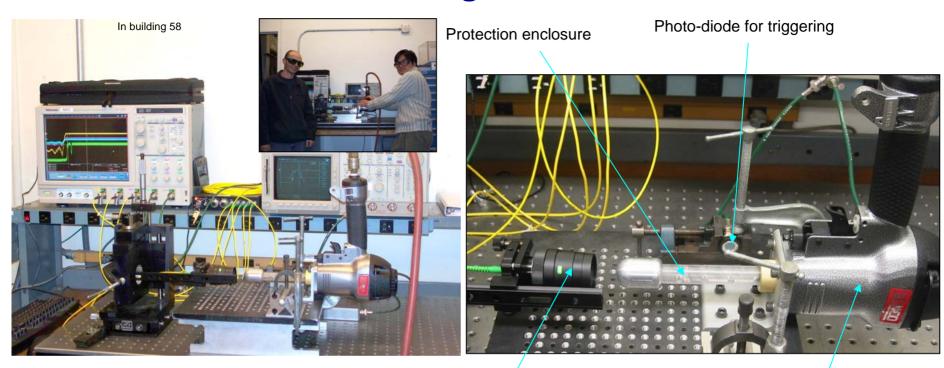

- -Two cameras used for beam diagnostics, target positioning and experimental snapshots
- -4 times magnification
- -Spatially calibrated
- -Camera resolution ~10 μm

D=100 mm (ordering)

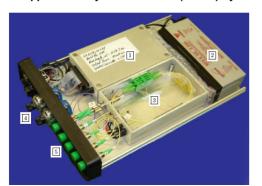

Tungsten target before shot (GSI)

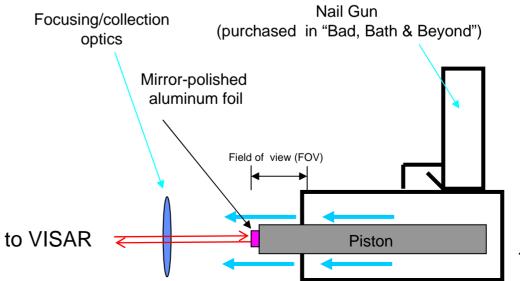

Testing VISAR

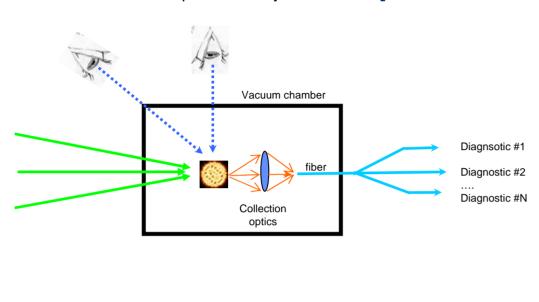

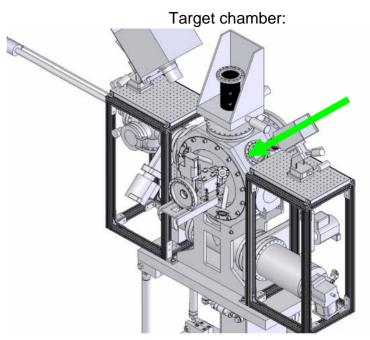

Experimental layout:

Experiment layout

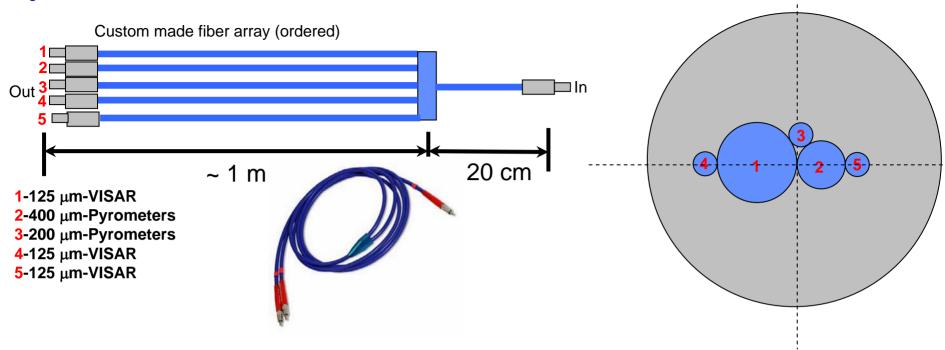

- -In first experiments target positioning with manual hexapod and collection optics with manual linear stages
- -Motorized in future (hexapods)
- -Positioning accuracy <10 μm

Pig tail

- -Signal levels (i.e. temperatures) are unknown!
- -Must be prepared for various scenarios.
- -Spatial resolution of probing optics is determined by the size of the fiber (from 50 μ m to 1000 μ m)

Worst case: low temperatures (<1000 K), fibers 1 (VISAR) and 4 (2-channel pyrometer)

<u>Ideal case</u>: high temperatures, fibers 5 (VISAR) and 2 (Streak pyrometer)

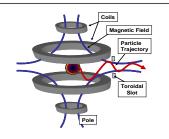

Benchmark of both pyrometers: fibers 1(2-channel pyrometer), 2 (Streak pyrometer) and 3 (VISAR).

IFE Reactor Core Magnetic Intervention (MI)

Solid Wall Magnetic Deflection

- •Cusp magnetic field stops the radially expanding ion shell
- ·Ion flux to wall is minimized
- Field is resistively dissipated in blanket/wall
- •Ions, at reduced energy and power, are directed through cusp poles and into mid-plane toroidal dumps

In Direct Drive (IFE) implosions, approximately 28% of energy released is carried by charged particles. The ion species include the usual DT and DD fusion reaction products and these charged particles represent the biggest "threat" to the survival of the first wall. To ease this threat, the concept of "Magnetic Intervention" has been proposed using a cusp shaped magnetic field to deflect the ions away from the first wall and into external dumps.

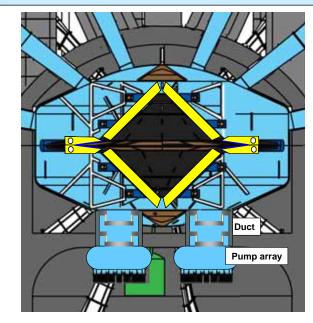

In a cusp geometry the field is zero at the target origin and presents a positive (convex) curvature to the expanding ion flux during the pulse. The interaction of the radially directed ions and electrons with this field will result in an induced rotational current in the expanding plasma. This induced current would be opposite that in the coils (clockwise in the upper hemisphere of the plasma, counterclockwise in the lower half) and thus would exclude the magnetic field from the interior of the expanding plasma. Because flux is excluded, the magnetic field is pushed outward and is compressed since it cannot move past the external cusp coils. The expansion will continue until the increased magnetic pressure is balanced by the expanding plasma pressure, i.e. the system produces a beta of ~1.0. If the chamber wall is made of a resistive material, such as SiC, some of the energy of expanding magnetic field can be dissipated in the wall material as heat, thus effectively converting into a volumetric deposition of that heat.

A cusp geometry has an open toroidal belt at the mid-plane and openings at the poles. The ions, with reduced energy eventually leak out these openings where their energy can be absorbed external to the chamber. Additional energy would be dissipated via Bremstralung and other photon radiation.

General Conceptual Arrangement for a Magnetic Intervention Chamber

Abstract

Magnetized Target Fusion (MTF) is a means to compress plasmas to fusion conditions that uses magnetic fields to greatly reduce electron thermal conduction, thereby greatly reducing compression power density requirements (1, 2). The compression is achieved by imploding the boundary, a metal shell. This effort pursues formation of the Field Reversed Configuration (FRC) type of magnetized plasma, and implosion of the metal shell by means of magnetic pressure from a high current flowing through the shell.

We reported at Megagauss 9 that we had shown experimentally (3) that we can use magnetic pressure from high current capacitor discharges to implode long cylindrical metal shells (liners) with size, symmetry, implosion velocity, and overall performance that is suitable for compression of Field Reversed Configurations (FRC's). We also presented considerations of using deformable liner – electrode contacts of Z-pinch geometry liners or theta pinch driven liners, in order to have axial access to inject FRC's and to have axial diagnostic access. Since then, we have experimentally implemented the Z-pinch discharge driven deformable liner – electrode contact, obtained full axial coverage radiography of such a liner implosion, and obtained 2D-MHD simulations for a variety of profiled thickness long cylindrical liners. The radiographic results indicate that at least 16 times radial compression of the inner surface of a 0.11 cm thick Al liner was achieved, with a symmetric implosion free of instability growth. We have also made progress in combining 2D-MHD simulations of FRC formation with imploding liner compression of FRC's. These indicate that capture of the injected FRC by the imploding liner can be achieved with suitable relative timing of the FRC formation and liner implosion discharges.

Since the compressed plasma and stagnating liner energy densities can exceed a megabar in MTF, this constitutes a potentially very useful High Energy Density Physics (HEDP) application.

Magnetized Plasma Compression (MPC) Also

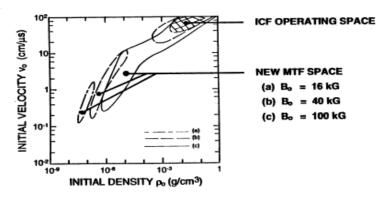

Known as Magnetized Target Fusion (MTF)

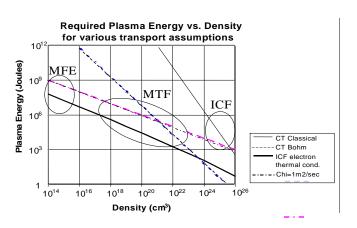

LANL

- Magnetized target fusion (MTF)
 identified in US and Russia as an
 alternate approach intermediate between
 magnetic and inertial fusion parameter
 regimes
- Closed magnetic field configurations reduce electron thermal conduction losses
- Enables (slower) adiabatic compression with modest driver requirements
- ~10X radial compression required
- Typical precompression plasma parameters: 200 eV, 10¹⁷ cm⁻³, 2 T

Since the compressed plasma energy densities exceed a megabar in MTF, this constitutes a potentially very useful High Energy Density Physics (HEDP) application.

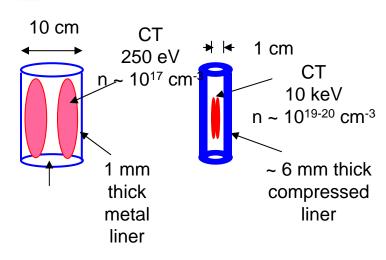

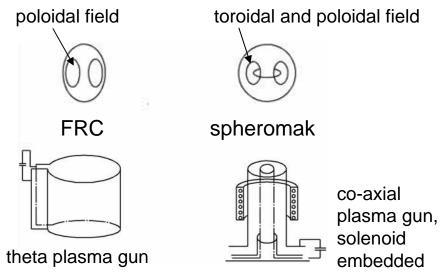

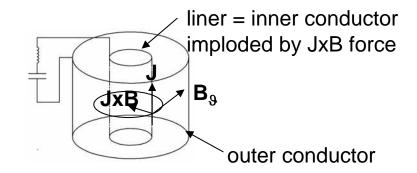

Magnetized Plasma Compression (MPC) can be achieved by imploding a metal liner with compact torus (CT) or a diffuse pinch plasma inside

- Two types of CT's are Field Reversed Configurations (FRCs) and spheromaks
- Both types of CT's can be formed by plasma guns and injected into liners
- Coaxial plasma gun without solenoid can form and inject diffuse Z-pinch into liner, which is also a magnetized plasma (with toroidal field only)
- Liner is imploded by JxB force from high current (> 10 megamp) discharge

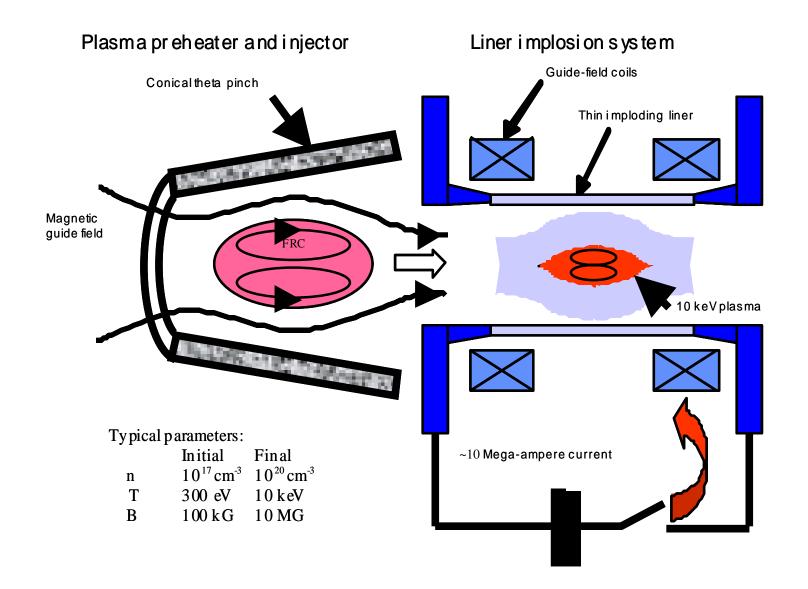

Elements Of Magnetized Plasma Compression, aka Magnetized Target Fusion (MTF)

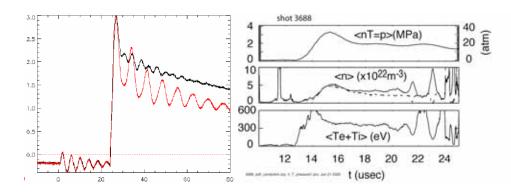

Recent progress in DOE_OFES sponsored effort: Lower upstream inductance crowbar switch reduced modulation of main theta discharge current

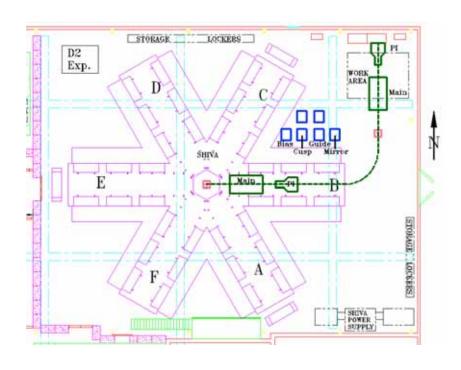

- This enabled formation of higher average density, better quality FRC's
- Multi-chord HeNe laser interferometry (By DEHP's Dr Ruden) obtained density distribution of FRC
- Tomography of such data (by Dr Ruden) enabled measurement of FRC rotation, assuming n=2 rotation
- magnetic field exclusion probes (by LANL) enabled measurement of plasma pressure
- density and pressure info enabled estimate of FRC temperature

These FRC formation experiments were done at LANL TA-35 using AFRL support for Pulsed Power and interferometry. See, for example, S. Zhang, T. P. Intrator, G. A. Wurden, W. J. Waganaar, J. M. Taccetti, R. Renneke, C. Grabowski, and E. L. Ruden, Phys. Plasmas 12, 052513 (2005). Such FRC experiments are to begin at AFRL adjacent to Shiva Star this year.

FRC formation hardware now exists in Shiva Star facility.

- Left: Planned layout of FRC formation banks and hardware in Shiva Star bay, in inserted and retracted positions.
- Right top to bottom: Main FRC formation bank (a single thiva star module), pre-ionization bank, initial magnetic field bias bank.

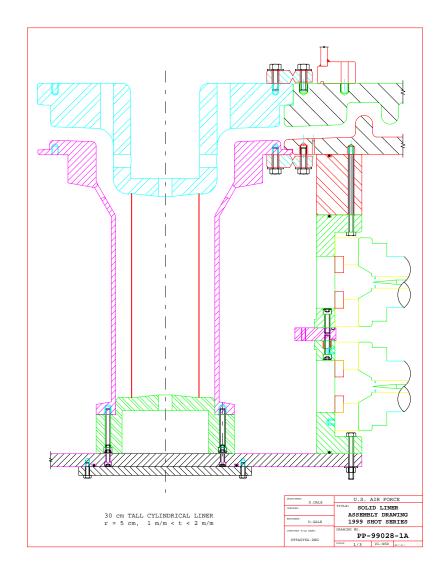

:

FRC Compatible Imploding Liner Hardware Design

- The 30 cm long liner implosion experiments extend our experience to longer liners
- The diagnostics on these initial shots include flash radiography, interior magnetic field compression, discharge current and voltage, and an interior instrumented impact package

Shiva Star Facility at AFRL

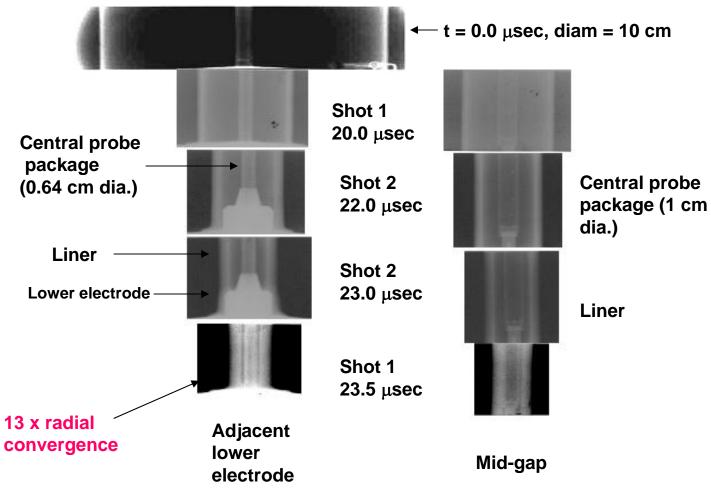

- 82 kV, 1300 uF, 44 nH for first Z-pinch driven long liner experiments
- ~12 Megamp, ~10 μ sec risetime discharge implodes 30 cm long, 10 cm diameter, 1.1 mm thick Al liner in 24 μ sec
- 4.4 MJ energy storage gives 1.5 MJ in liner KE

Shiva Star Capacitor Bank (up to 9 Megajoules, 3 µsec) available now for implosion - compression experiments

Radiographs from FRC compatible Liner Implosion on Shiva Star

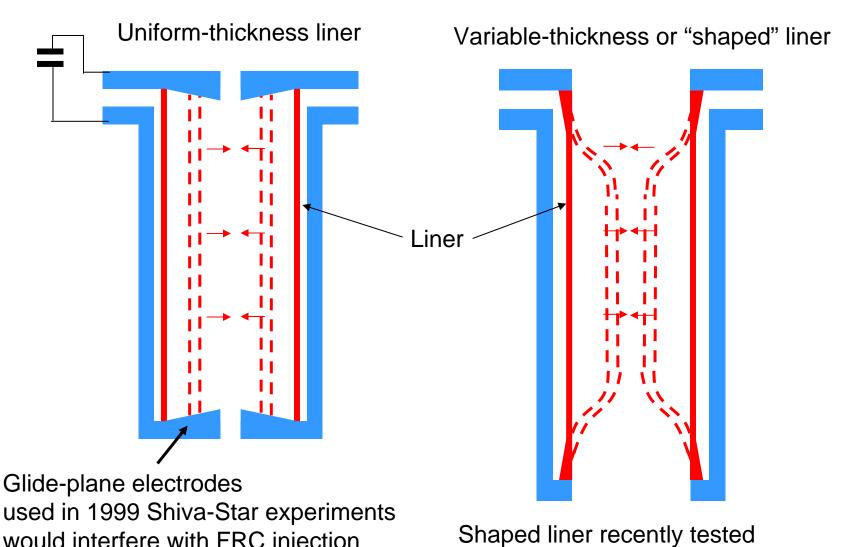

Achieved velocity, radial convergence, symmetry, stability needed for compression of FRC's to MPC conditions

would interfere with FRC injection

Connecting current to the liner

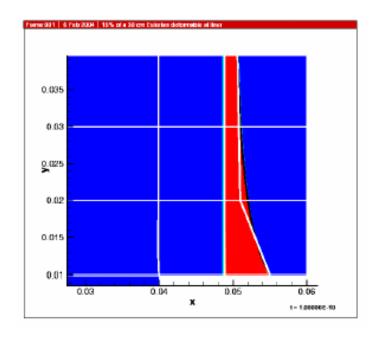

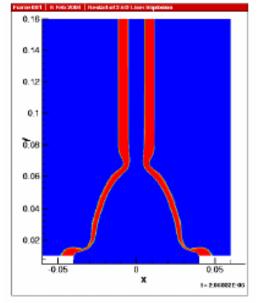

2D-MHD simulations indicate feasibilty of deformable liner-electrode concept

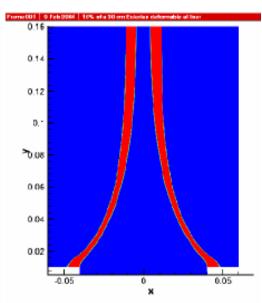

Double frustrum and smooth liner initial thickness profiles

Double frustrum profiled liner density contours at ~ 1 µs before peak compression

Smooth profiled liner density contours at $\sim 1~\mu s$ before peak compression

Deformable Liner-Electrode Contacts Offer Advantages in Purity of the Compressed Plasma and Diagnostics Access for Z-pinch Driven Liner; these examples are for 8 cm diameter electrode apertures

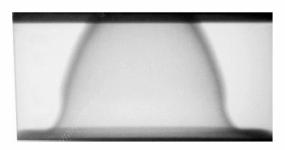

Deformable contact liner implosion performed with 8 cm diameter electrode apertures; results indicate that Z-pinch imploded liner approach is feasible

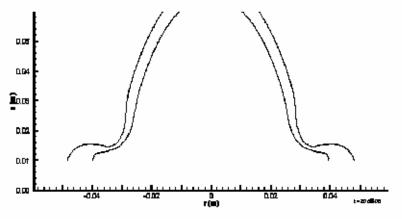

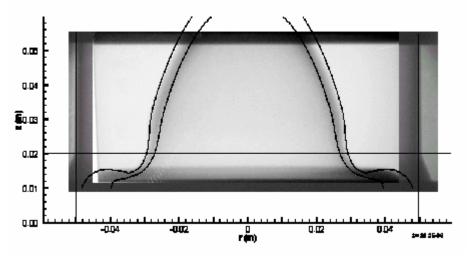

Static radiograph of portion of liner adjacent to electrode, prior to experiment. Inner diameter = 9.78 cm.

Experimental radiograph for portion of liner adjacent to electrode, at 22 µs after start of current, approximately 0.5 µs prior to peak compression. Bottom of liner to top of field of view is approximately 4.5 cm.

2D-MHD simulated density contours for similar parameter liner implosion, at 0.5 us before stagnation.

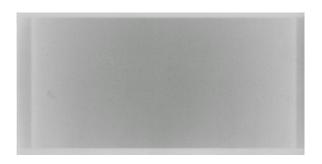

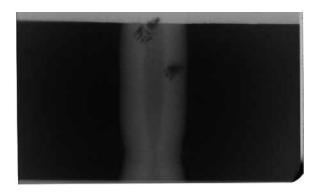

Overlay of 2D-MHD simulation density contours and radiographs at approximately same size scales. 14

Mid-gap radiograph indicates ~ 17 x radial compression of inner surface

Top: radiograph of liner at t=0, near mid-gap, ID = 9.78 cm, OD = 10.0 cm.

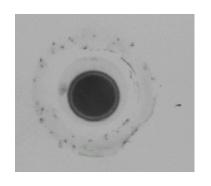

Bottom: radiograph of liner at $t=22~\mu sec$, near mid-gap. ID of non-m=0 portion $\cong 0.58$ cm, corresponding to radial compression of inner surface ~ 17 . We believe that the m=0 portion is right at mid-gap. If there had been an FRC inside, it would be compressed > 10x radially prior to significant growth of this instability.

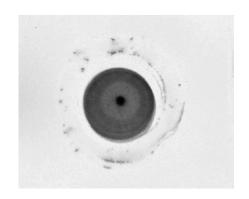

We suspect this late m = 0 feature is due to release of initial axial compression, combined with thickness derivative discontinuity (from double frustrum thickness profile) at 9 cm from mid-gap. Both the initial axial compression and the thickness derivative can be removed by design change.

Axial view fast optical photos indicate symmetric implosion of inner surface of liner with inner diameter consistent with simulation

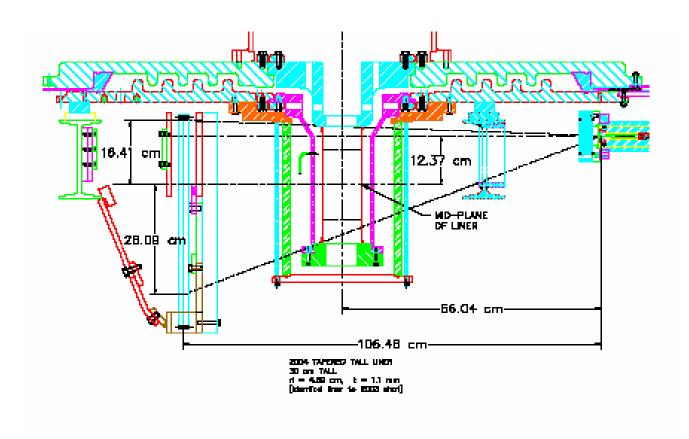

Left: 200 nanosec optical framing photo, axial view, of load. Inner diameter of opening is 8.0 cm. Photo used Xenon flash backlighting.

Right: 200 nanosec optical framing photo, axial view, of load at 21µsec into implosion discharge. Inner diameter of smallest part of liner (most imploded part) is 1.5 cm.

Deformable contact liner experiment geometry for near full axial coverage radiography

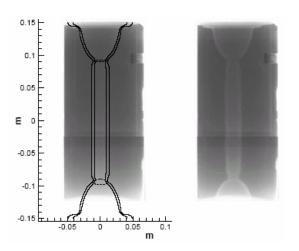

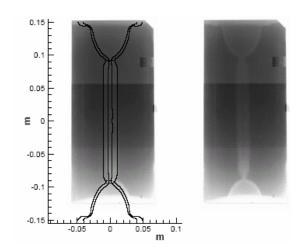

This experiment used the same liner thickness vs axial position, and same capacitor discharge parameters, as for the partial axial coverage radiography experiment.

Implosion of deformable liner suitable for compressing FRC's to MTF conditions demonstrated

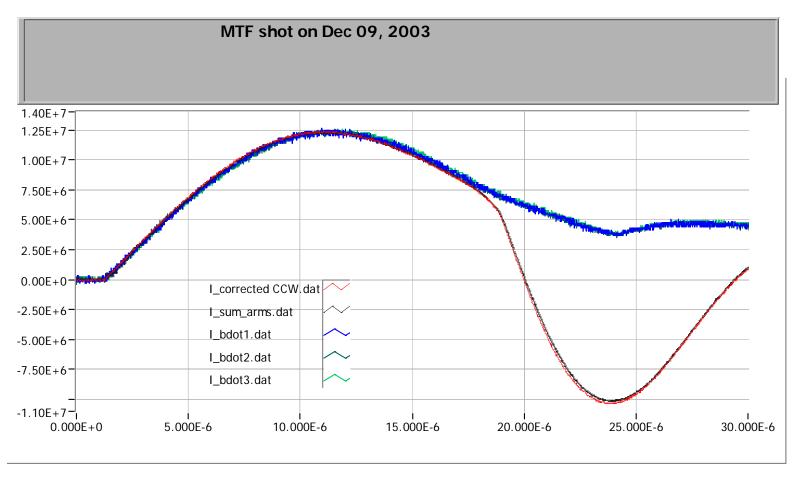

- Radiographs and 2D-MHD simulations of implosion of 30 cm long, ~
 1mm thick, 5 cm radius Al liner indicate feasibility of deformable liner electrode contact.
- This enables 8 cm diameter electrode apertures, sufficient for FRC injection into liner interior.
- Left: 21 µs after start of current. Right: 22 µs after start of current.
- Driven by 12 megamp Shiva Star axial discharge thru liner.

Normal current delivery to liner and symmetry were obtained for experimental Bi-frustrum profile)case

Current peaked at ~ 12 megamps, at ~ 10 µs after start of current rise. Insulator crowbar occurred at ~ 17 µs, as expected.

Alternative liner thickness vs profiles are being examined via Mach2 simulations

A family of such simulations uses an analytic profile which includes Gaussian thinning region a few cm from electrodes

$$r(z) = \left[R_3 + \left(\frac{A}{B-z}\right)^{1/n} + \left(\frac{A}{B+z}\right)^{1/n}\right] \left[1 - \alpha \exp\left[-\left(\frac{z - z_{00}}{\Delta}\right)^2\right]\right]$$

 Z_0 = distance from liner midplane. Z_0 = 11.5 corresponds to 3.5 cm up from electrode. Z_{00} = 3.5

 Δ is the half width at half max and α is a measure of the amplitude.

Other parameters are defined in following table (next slide)

Deformable liner thickness profile parameters

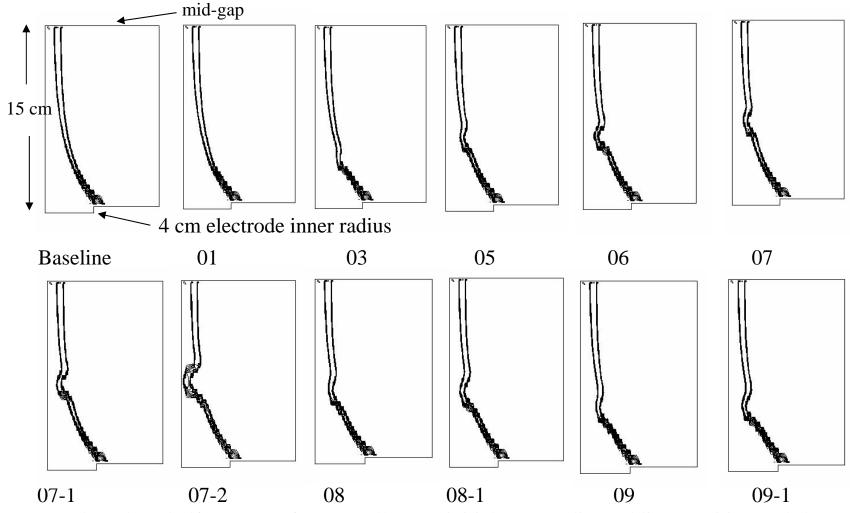

Case	A	n	R_0	R ₁	\mathbf{z}_1	z_0	α	Δ	
Base line	1.3	0.5	5.0	5.5	15	11.5	0.0	1.0

2D-MHD simulations indicate that use of Gaussian thinning regions a few cm from electrodes controls divergence of liner ends; variants of this are being investigated computationally

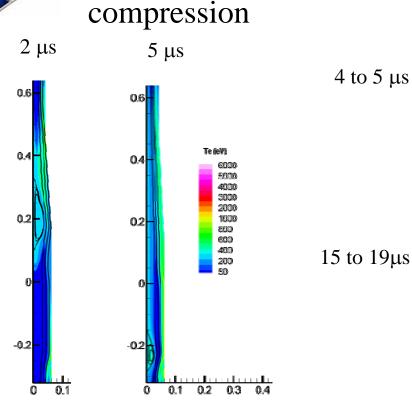

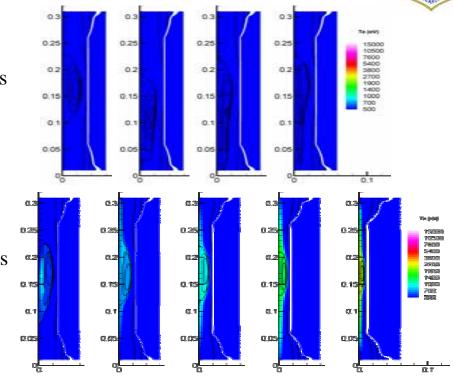

Contour plots show half (15 cm) of 30 cm tall, 5 cm initial outer radius, Al liner position and shape at 21 microseconds after start of 1300 microfarad, 80 KV, 44 nanoHenry initial inductance Shiva Star discharge,²² with standard safety fuse. Initial liner thickness is 1.1 mm at mid-gap (15 cm above lower electrode).

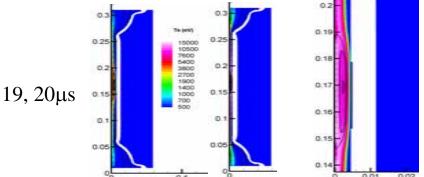

Temperature contours from Mach2 2D-MHD simulations of FRC formation, translation, and liner

FRC initially moving down. Eulerian after 17.5 μ s. FRC captured with liner implosion discharge started 9 μ s prior to FRC main theta discharge. Delay window for capture ~ 1 μ s Calculated FRC T > 8 KeV.

Technical Issues - MPC

- Principal technical issue is propagation of liner material into plasma (though 2-D MHD simulations look promising, they may not be at sufficient resolution and 3-D effects need study)
 - Capacitor driven experiments can answer this issue
- Other technical issues and options:
 - Field topology (diffuse Z pinch vs compact torus with poloidal and toroidal field vs compact torus with only poloidal field)
 - Injected vs *in-situ* formation of pre-compression plasma
 - Spherical vs cylindrical liner
 - Fusion yield vs driver energy, size

Concluding remarks

- By use of liner thickness vs axial position profiling, it appears possible to use a Z-pinch type discharge to compress ~ mm thick Al shells with sufficient radial convergence (>10 x inner radius), symmetry, and velocity (~ 0.5 cm/μs), and with sufficiently large electrode apertures, for injection of FRC's and for their subsequent compression to Magnetized Target Fusion (MTF) conditions.
- Preparation of FRC formation apparatus adjacent to Shiva Star capacitor bank and integration with imploding liner apparatus is progressing.
- Combined 2D-MHD simulation of FRC formation and compression by imploding liner indicates that compression and heating of FRC from ~ 10^17 ions/cc, ~ 200 eV to ~ 10^19 ions/cc, several KeV is feasible with existing capacitor banks.

Can Imploding Liner Magnetized Plasma Compression Be Made Repetitive?

- Implosion-compression of several-cm-radius shells on the 1 to 10 microsecond time scale can be used for magnetized target fusion (MTF)
- This can be done in a manner with standoff of the driver, e.g., using arrays
 of laser or particle beams, which enables repetitive operation (for power
 plants or propulsion)
 - Similar to inertial confinement fusion (ICF) drivers, but with 10³ to 10⁴ times slower pulses, hence easier
- There are also schemes for repetitive operation of magnetic pressure driven liner implosions (R.W. Moses et al, LA-7683-MS, 1979, and G.E.Rochau et al, presented at IEEE-Pulsed Power Plasma Sciences Conference, Las Vegas, Nevada, June 2001, O5D7, p.592, IEEE-PPPS-2001 Conference Record-Abstracts, IEEE Catalog 01CH37255), and for pneumatic pressure driven implosions of rotationally stabilized, re-usable liquid Li liners (P.J. Turchi et al, Phys. Rev. Lett. 36, 1613 (1976))
- A plasma jet spherical array compression scheme has also been proposed (Y.C.F.Thio et al, Proceedings of Second Symposium of Current Trends in International Fusion Research, 1999)
- Single shot versions of such implosion-compression can be done now via magnetic pressure implosions, using our existing large capacitor bank
- Such single shot implosion-compression experiments can be used to investigate critical technical issues before developing and building more expensive, repetitive drivers

Failure Strength Measurements of VPS Tungsten Coatings for HAPL First Wall Armor

Jaafar El-Awady, Hyoungil Kim, Jennifer Quan, Shahram Sharafat, Vijay Gupta, and Nasr Ghoniem

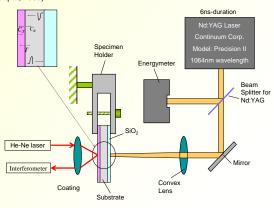

Mechanical and Aerospace Engineering Department, University of California Los Angeles (UCLA)

Introduction

- The High Average Power Laser (HAPL) project is pursuing development of an IFE power reactor using a solid First Wall Chamber. Tungsten is the primary candidate for armor material protecting the low activation ferritic steel first wall (FW) chamber.
- The tungsten armor is less than 1-mm thick and is applied by vacuum plasma spraying (VPS).
- Adhesion of the tungsten-armor to the ferritic steel is critical, thus the interfacial strength between the W-armor and the substrate is measured using a state-of-the-art technology developed at UCLA.
- VPS W-coated steel samples were tested using the laser spallation technique and the failure strength of the W-coatings was quantitatively determined. It is shown that the interfacial strength between ferritic steel and the Wcoating is much greater than the failure strength of the W-coating.

The Laser Spallation Interferometer Experiment

- The melting-induced expansion ferritic steel under confinement of SiO₂ generates a compressive stress pulse that propagates towards the bonding interface.
- This compressive stress wave reflects as a tensile stress wave from the free surface of the coating and leads to its spallation at a sufficiently high amplitude.
- This critical tensile stress, causing failure of the coating, is obtained by measuring the transient displacement history of the coating's free surface (induced during pulse reflection) by using an optical interferometer (Pronin and Gupta, 1993).

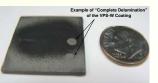

Experimental Results

- The tungsten/F82H sample was impinged with the laser beam at different locations and different laser intensities to determine the critical energy that would result in failure of the coating.
- The sample was cross-sectioned at the locations of impingement to detect any interlayer failure in coating layer.
- The following table shows the effect of increasing laser intensity on the failure
 of the coating:

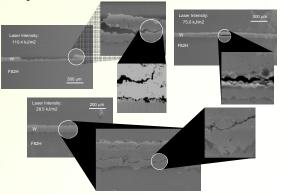

Laser Intensity	22.9 kJ/m²	25.6 kJ/m ²	28.5 kJ/m ²	75.0 kJ/m²	110.4 kJ/m²
Type of Failure	No Failure		nucleated in	Crack opening and popping of the coating	Complete delamination of the coating

. The impinged sample:

 The following figures are SEM micrographs showing the failure in the W-armor coating for different laser intensities.

Cracks nucleate in the area located one third of the distance between the W-F82H interface and the coating free surface.

Conclusions

- The laser spallation technique was used to quantify the failure strength of the VPS W on F82H.
- It is observed that the failure of the sample occurs within the W-coating and not at the interface. This is due to that the morphology of the VPS coating (splat formations)
- The failure strength estimates depends on the mechanical properties of the coating (VPS – coating properties), such as density, Young's modulus, Poisson's ratio need to be experimentally measured for more accurate failure strength estimates.
- Further analysis taking into account the morphology of the VPS coating failure strength may differ.

Specimen and Materials Properties

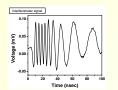

- The Vacuum Plasma Sprayed (VPS) samples were supplied by PPI (S. O'Dell).
- W-Coatings were polished to ~65 mm thickness at ORNL (G. Romanoski)
- Elastic properties of the coating depend on the coating process. Plasma Spraying results in a lower density, p, and a lower Young's Modulus, E.
- The material properties for the W-coating and the F82H substrate are shown in the following table:

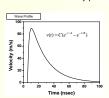

Properties	F82H	W (Bulk)	80% Dense W (VPS)
Young's Modulus (GPa)	217	410	54*
Poisson's ratio	0.29	0.29	0.1
Density (kg/m³)	7870	19246	15397
Wave speed (km/s)	6.011	5,284	1.894

*Matejicek, 2005

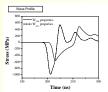

Failure Strength Measurements

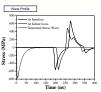

- The critical laser intensity, 28.5 kJ/m², at which the first evidences of crack nucleation appears in the coating is used to calculate the failure strength.
- The generated compression pulse at this critical laser intensity is determined experimentally by monitoring the transient displacement history of the substrates free surface by using an optical interferometer. The corresponding stress wave profile is then derived using standard interferometery procedures.

 Finally, the failure strength is determined, at the location of crack nucleation, by reading the velocity history into a finite element code (ANSYS).

 Based on the idealistic assumptions, the failure strength of the VPS W-coating, was calculated to be in the following range:

 $450MPa \le \sigma_c \le 550MPa$

- ⁴ Naval Research Laboratory

- The Receiving and Analysis System (RAS) designed to receive the target chamber effluent gas stream, and hold the gas temporarily for analysis.
- The Bed Regeneration System (BRS) designed to provide a method for regenerating the Molecular Sieve Dryer, Nickel (Ni), and ZrFe beds in both the RCS and the GCS, and the Molecular Sieve Dryer and the Nickel beds in the HPS.
- The Hydrogen Purification System (HPS) configured to receive the target chamber effluent gas stream and separate the hydrogen isotopes from that gas stream with a DF of greater than (>)10⁴.
- The Residual Cleanup System (RCS) configured to remove tritium from the residual gas in the Gas Holding Tanks.

- The Isotopic Separation System (ISS) for the IFE target chamber exhaust is configured to receive hydrogen isotopes from the HPS and separate them using cryogenic distillation into hydrogen, deuterium, and tritium (or a deuterium-tritium mix).
- The Glovebox Cleanup System (GCS) designed to remove tritium and maintain a dry argon atmosphere in each of the facility glove boxes.
- The Analytic and Delivery System (ADS) designed to receive deuterium, tritium, and/or a deuterium-tritium mix from the ISS.
- The Room Detritiation System (RDS) designed to detritiate a room in the event that the tritium level in that room exceeds a predetermined value. Additionally the RDS can be used for target chamber leak mitigation.

Path Forward: The next step in the development of the FRS design is to analyze the interactions between this subsystem and other systems within the reactor complex, including target design and target manufacture. Currently different breeding blanket concepts are being evaluated to best fit the requirements of fueling. Of paramount importance is the safe operations and efficiency of this system as it integrates into the larger reactor complex. To the highest extent possible, proven commercial off-the-shelf (COTS) technologies are incorporated into the design for the purpose of providing a highly reliable and cost effective system. As a result of implementing these strategies the FRS is not a pacing item in the development of a closed fuel loop IFE power reactor.

Target Fabrication Status for the HAPL Program

Introduction

The current high-gain HAPL target design is a 4.6 mm diameter foam capsule

Important Specifications Foam shell:

Out of round - <1% Wall uniformity - <1-3%

Plastic Overcoating:

Gas tight Smooth (50 nm RMS)

Foam Layer Material

Resorcinol Formaldehyde (RF)

CHO polymer

Very small pore size (~10-100 nm)

Aqueous precursor

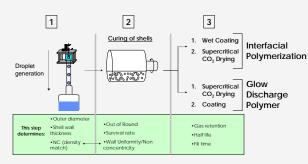

Divinyl Benzene

CH polymer

Large pore size (~1000 nm)

Organic precursor

Foam Shell Fabrication Process

- 1. A triple orifice droplet generator is used to form an emulsion of spherical shells out of the liquid precursor of the shell wall
- 2. While the shells are gelling, they are agitated in order to center the inner droplet - creating a uniform shell wall
- 3. The shells can be coated before or after drying

Glow discharge polymer allows the coating of shells after they have been dried.

- 1) C.P. Lee and T.G. Wang, J. Fluid Mech. 188, 441 (1988).
- 2) T. Norimatsu, Fusion Technol. 35, 147 (1999).
- 3) B. McQuillan et al., 15th HAPL Workshop August 2006.
- 4) Roark and Young, Formulas for Stress and Strain (1982)

Wall Uniformity

The current foam wall uniformity specification is described in terms of shell Non-Concentricity (NC)

Theories of centering

Modes of Oscillations 1,2

Rotational Shear: Journal Bearing Model 3

These models indicate several important parameters for centering of the inner droplet during curing:

Surface tension - changes oscillation of shell, increased surface tension also improves sphericity of shell

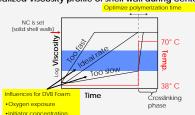

Density mismatch - inner fluid and shell wall densities should be very similar,

Deformation - Rate of collisions (size of container, #of shells, etc.)

Viscosity - dampens out movement of inner droplet in shell; increases centering force

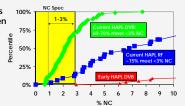

Gelation time - related to viscosity; inner droplet must be given time to center, but must be short enough to avoid compromising shell integrity

Idealized viscosity profile of shell wall during centering process

An optimization of parameters, has been done for large DVB shells and is beginning for large RF shells

Overcoating

- Must be gas tight and smooth (<50nm RMS)
- Pressure differentials in the coating process can cause leaks

One challenge of fabricating a HAPL overcoat is the high aspect ratio required of the polymer coating

•The high aspect ratio causes the shells to have a low buckle strength

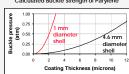

Buckle strength Formula for a Thin Shell

$$\Delta P_{buckle} = \frac{2 \cdot E}{\sqrt{3 \cdot \left(1 - v^2\right)}} \left(\frac{w}{r}\right)^2$$

suggests buckle may be even les

 $\Delta P_{burble} = 0.365 E \left(\frac{W}{F}\right)^2$

Calculated Buckle Strength of Parylene

The Burst Strenath is higher

 $\Delta P_{burst} = S \cdot \frac{2w}{r}$ ~5-10 atm

The burst strength depends linearly on the aspect ratio, allowing the shell to be less sensitive to overpressure

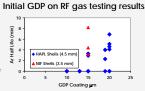

Elastic (tensile) modulus (E) of various polymers are simila

E (kpsi)	Low buckle strength will be a
260-551	problem with an
189 - 580	high aspect ratio
348	shell with a polymer coating
	E (kpsi) 260-551 189 - 580

Primary Coating Technique:

Glow Discharge Polymer (GDP)

- Compatible with small pore size of R/F
- · Improved surface roughness Successful on smaller R/F shells for OMEGA
- "Dry" coating
- · Coating deposited after supercritical
- · Avoids burst and buckle pressures on the shell from drying process

Alternate Techniques Possible for DVB and RF: Interfacial Polymerization (PVP)

Wet coating chemistry

Requires solvent exchanges and drying for foam shell application

2 layer coatings - (PVP/GDP)

Interfacial layer covers the larger pores, GDP seals shells

Conclusion

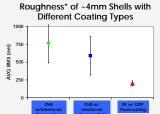

- DVB Shell Uniformity The shells have acceptable yield after optimizing conditions
- RF Shell Uniformity- Continuing work on improving the wall uniformity
 - Increasing interfacial tension between shell wall and outer fluid

· Optimizing the inner & outer oil densities & run conditions

- Has been demonstrated to improve the NC in 1mm diameter RF shells
- · A Glow Discharge Polymer on RF Foam is a promising pathway for a smooth, gastight coating

Surface Smoothness

Coated R/F foam shells are smoother than overcoated DVB shells to date

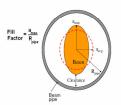

Measurement of Electron Clouds in Heavy-Ion Beam Drivers for HEDP and IFE*

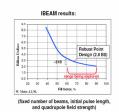

M. KIREEFF COVO, LLNL and UCB, A.W. MOLVIK, R. COHEN, A. FRIEDMAN, LLNL, P. A. SEIDL, J-L. VAY, F. BIENIOSEK, B. G. LOGAN, LBNL, J. VUJIC, UCB

In order to focus ion beams to high-power density for high-energy-density physics studies and ultimately inertial-fusion power production, we must be able to transport high-current, high-energy beams while preserving their brightness (minimizing their emittance). With this aim, the US Heavy Ion Fusion Sciences program developed the High Current Experiment (HCX), consisting of a single beam injector, an electrostatic matching section, and electrostatic and magnetic quadrupole transport sections, that provides a K+ ion beam current of 183 mA for 5 µs. It constitutes a unique facility to study the physics of high brightness transport under conditions of a large "fill factor" (ratio of beam radius to tube radius), as necessary for cost minimization. A deleterious effect that can arise when ions strike the pipe wall is the development of a stray "Electron Cloud," a recognized problem that limits the current and brightness on many large accelerators. Our goal here is to understand this effect using new diagnostics coupled with state-of-the-art simulations, and to develop techniques for minimizing such clouds.

* This work performed under the auspices of the U.S Department of Energy by University of California, Lawrence Livermore and Lawrence Berkeley National Laboratories under contracts No. W-7405-Eng-48 and DE-AC02-05CH11231.

Fusion power plant cost reduced by high fill factor beams

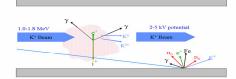

• Cost of a Fusion Power Plant is function of fill

At the range of interest (beyond 60%), the beam runs closer to the walls and starts to produce secondary electrons and desorbed gas, which could move to the beam path and be ionized. The electrons produced are trapped by the space charge beam potential. We start to lose control of the beam transport and produce more secondary electrons and desorbed gas. It is the beginning of the "Electron Cloud Effect".

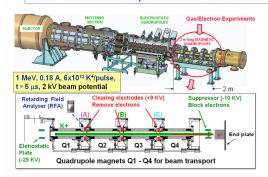

Physical mechanism of electron production

Beam hitting gas or walls creates electrons and gas

At grazing incidence, each ion of K+ ion with energy of 1MeV desorbs 10,000 molecules of gas and produces 100 electrons, which can multiply.

HCX instrumented to perform Electron Cloud density accumulation experiments

Electron Clouds were observed inside the Magnetic transport Section

The magnetic transport section can work as an electron trap device. Electrons can be confined axially between the suppressor at one end and the last electrostatic quadrupole plate at the other end, and radially by the beam space-charge potential of 2 KeV. Clearing electrodes and suppressor can work as switches to allow electron accumulation experiments.

Absolute measurement of Electron Cloud density*

*M. Kireeff Covo et al., Phys. Rev. Lett. 97, 054801 (2006)

 Retarding Field Analyzer (RFA) measures depressed beam potential by electron accumulation

The produced cold ions are expelled by the beam space charge, so the maximum energy of the ion is given by the beam potential. As the RFA is a high-pass energy filter, when the RFA does not collect more ions is the moment that the beam potential decayed to the retarding grid bias.

Ion energy does

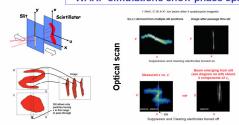

not surmount the

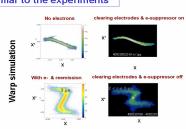

etarding grid bias

Measurements of Electron Cloud accumulation

We used clearing electrodes B and C, and suppressor S to control electron accumulation. If we turn on all the electrodes (B, C and S on), we minimize electrons from all sources and the beam potential has the same slope of the Faraday cup current, showing that the beam neutralization remains constant. When we turn off the clearing electrodes (B, C off, S on), we see a higher slope, showing the beam potential depressed by the Electron Cloud accumulation. Finally, if we also turn off the suppressor (B, C, S off) we allow electrons from end plate to drift upstream and fill the quadrupole magnets.

WARP simulations show phase space similar to the experiments

Conclusions

- The High-Current Experiment (HCX) is an unique platform to explore sources of electron generation and accumulation in positively charged beams.
- We developed a new technique to measure electron accumulation by probing the depressed beam potential with expelled ions produced from the interaction of the beam with the background gas. The simulations show not only the qualitative aspects of the experiments, but also some unanticipated physical effects from the beam degradation by the Electron Cloud accumulation. Such degradation must be minimized, by techniques such as we are developing, in order to focus beams to high power density.

Beam Focusing Concept for a Modular Heavy Ion Driver

by

Edward Lee

Lawrence Berkeley National Laboratory

for

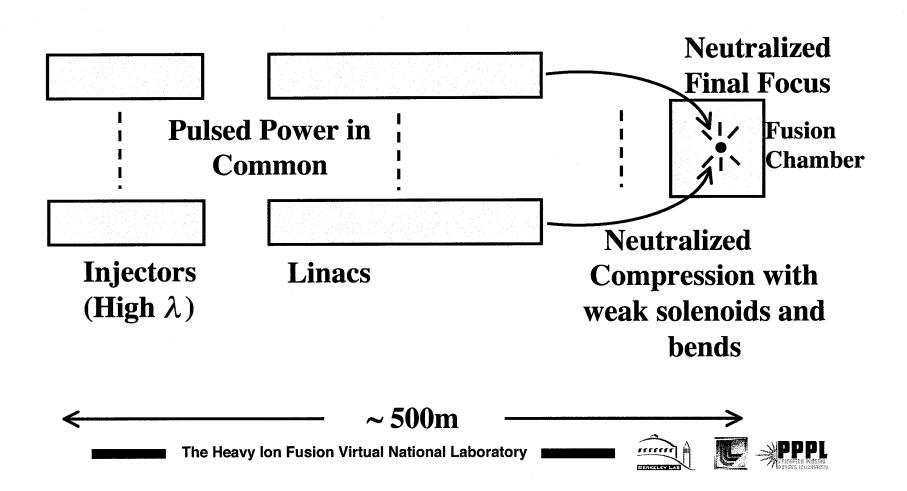

The IFE Science and Technology Strategic Planning Workshop

April 24 - 27, 2007

A modular heavy ion driver uses many synchronized linacs $(N \approx 20-100)$ at relatively low kinetic energy $(E \approx 100-1000 \, MeV)$

Why Consider Solenoids for HIF Now?

• Solenoids transport higher line charge density beams <u>at low kinetic energy</u> than quadrupoles:

$$T \lesssim 16 MeV$$
 C_s^+
 $T \lesssim 40 MeV$ N_e^+

- Solenoids are essential for several high current source concepts
- Solenoids may aid <u>neutralized</u> drift compression
- Final Focus for neutralized, highly stripped beams is simplified
- Transverse dynamics in vacuum transport is more stable and has less "flutter" than with quadrupoles and electron production from pipe walls may be suppressed

These Solenoid Features Suggest A Modular Driver Architecture

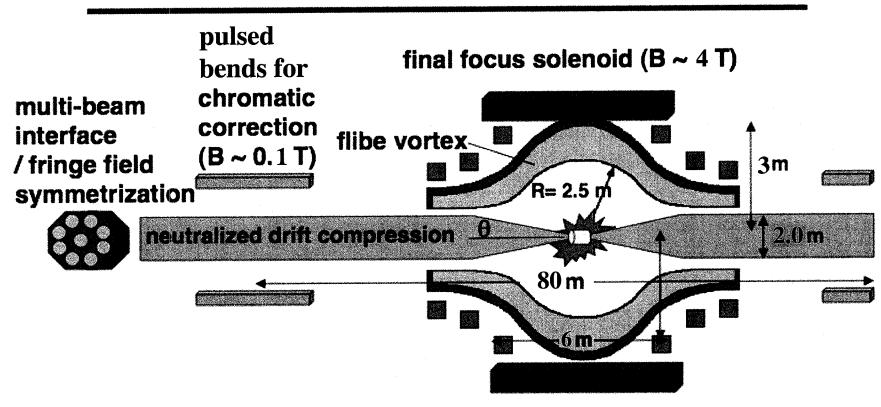

- •N = 20-100 parallel separate accelerators in two opposed clusters
- Moderate mass ions are accelerated to relatively low energies (e.g. 200-300 MeV N_e^+) or 500 MeV K_r^{+8}
- High line charge density is transported by solenoids during acceleration ($\lambda \approx 5 20 \ \mu C/m$)
- Final Compression, Final Focus and Chamber Transport are neutralized to accommodate very high final line change densities

Modularity allows an attractive development path

A solenoid-based final focus system for a modular driver has attractive features

Large cone angle $\theta \sim 200$ mr produces a small spot (~ 1 mm) on target for ϵ ~ 4×10^{-6} m-rad

Moderate fields allow normal magnets

Highly stripped ions (eg q=+8)

Fringe field aberrations minor

A modular driver may simultaneously accelerate several ion species

- Useful for "pulse foot" or target interaction at different latitudes
- All ions must have about the same magnetic rigidity

rigidity =
$$\frac{\text{momentum}}{\text{charge}} = B\rho = 3.107 \beta \gamma \frac{A}{q}$$

Example (B ρ = 3.7T - m): range in cold carbon

320MeV Xe+8

 $.003 \text{gm/cm}^2$

500MeV Kr+8

 $.006\,\mathrm{gm/cm^2}$

1040MeV Ar+8

 $.1 \text{gm/cm}^2$

Features of a final focus system

- Low magnetic rigidity → solenoids may be used
- Require very high degree of charge and current neutrality
- Beams injected off-axis (~1.0m) are all focused to an on-axis target $\longrightarrow \frac{\varepsilon}{\theta} \approx \text{rspot}$
- Small solid angle for neutron escape
- Time-dependent kicker compensates for momentum variation within a pulse
- Beam spot radius $r_s \le 1.0mm$ (direct drive) for plausible emittance and thermal momentum spread
- Capability for rapidly rotating spot position on fusion target

Focal Design Features (cont.)

- Parallel-to-Point Focus on axis includes effects on aberrations
- Weak solenoids produce an intermediate focus good for neutron confinement and corrections for momentum variation
- Strong central solenoid produces a small beam spot radius
- Large final angles (100 300mr)

Issues

- Does a beam's emittance and charge state remain constant while traversing the gas density profile required for neutralization?
- Are beam instabilities (hose, two-stream, ...) benign in their effect on focusing?
- Can a fast kicker be designed with the required low jitter $(\Delta B/B \le 10^{-3})$?
- Can a high field solenoid operate close to a fusion chamber?
- Can high charge state ion sources produce beams with the desired current and quality?

An Ion is Focused by the Interaction of Its Azimuthal Velocity with Bz

$$F_r = qe(E_r + v_\theta B_z)$$
$$F_\theta = -qev_z B_r$$

- Azimuthal velocity v_{θ} is impressed on an ion when it passes through the fringe field.
- A beam spins in a cold equilibrium with space charge field E_r balanced by Bz (Brillouin flow).
- This is not like a magnetized plasma or most nonneutral plasma experiments.
- Dynamics are simplified in the Larmor frame (rotates at $\theta = -\omega_c/2$)

Computation of ion orbits must include geometric and fringe field aberations

Assuming charge and current neutrality:

$$\frac{d^2x}{dz^2} = \frac{\left(1 + x'^2 + y'^2\right)^{1/2}}{B\rho} \left[y'B_z - \left(1 + x'^2\right)B_y + x'y'B_x \right]$$

$$\frac{d^2y}{dz^2} = -\frac{\left(1 + x'^2 + y'^2\right)^{1/2}}{B\rho} \left[x'B_z - \left(1 + y'^2\right)B_x + x'y'B_y \right]$$

$$B_z = B_o(z) - \frac{B_o''r^2}{4} + \frac{B_o''''r^4}{64} - \dots$$

$$B_r = -\frac{B_o'r}{2} + \frac{B_o'''r^3}{16} - \frac{B'''''r^3}{384} + \dots$$

$$B_{x} = \frac{xB_{r}}{r} - \frac{B_{\theta}y}{r}$$

$$Pulsed kicker$$

$$B_{y} = \frac{yB_{r}}{r} + \frac{B_{\theta}x}{r}$$

$$\mathbf{B}_0 = \sum_{i} \mathbf{B}_0^{Lens} (z - Pi)$$

A New, "First Principles" Look at the Parameter Space for Controlled Thermonuclear Fusion

Irvin R. (Irv) Lindemuth Richard E. (Dick) Siemon

Department of Physics University of Nevada Reno NV

Poster paper presented at the IFE Science and Technology Strategic Planning Workshop April 24-27, 2007 San Ramon CA

Abstract

The conventional pathways to fusion—MCF and ICF—have proven to be very long and very expensive. These two approaches are now embodied in two multi-billion-dollar facilities, ITER for MCF and NIF for ICF. These two approaches differ by many orders of magnitude in fundamental physical quantities (density, burn time, fuel pressure, and fuel volume). Given such large differences, it is reasonable to ask an obvious question:

is there anything in between the extremes of MCF and ICF?

In this paper, we take a new "first principles" look at the conditions under which fusion can occur. We review the fuel conditions (e.g., confinement time, density, temperature) that must be met to achieve significant fusion energy release. By comparing loss rates with fusion rates, we can identify the density-temperature space where fusion gain can be achieved. This simple analysis offers a general understanding of the extreme differences between the conventional approaches to controlled fusion, MCF and ICF. The analysis shows that the constraint of steady-state operation forces MCF to operate at the low end of the density spectrum and that the constraint of unmagnetized fuel forces ICF to operate at the high end. Most importantly, the analysis shows that using a magnetic field in the fusion fuel allows operation at an intermediate density (10e18-10e22/cm3), a density range that has many attractive features and potentially overcomes some of the obstacles, particularly cost, faced by the more conventional approaches.

FUSION 101--what they should have taught us in freshman physics > 40 years ago.

- What fusion fuel density, temperature, magnetic field, etc. are required to achieve fusion?
- Why is the National Ignition Facility (NIF) forced to operate at very high density?
- Why is the International Toroidal Experimental Reactor (ITER) forced to operate at low density?
- Why are there so many orders of magnitude in density, volume, etc., between NIF and ITER?
- Why is fusion so costly?
- Has all the fusion parameter space been explored, or are there promising, but unexplored, regions in parameter space?

Thermonuclear fusion occurs at high temperature.

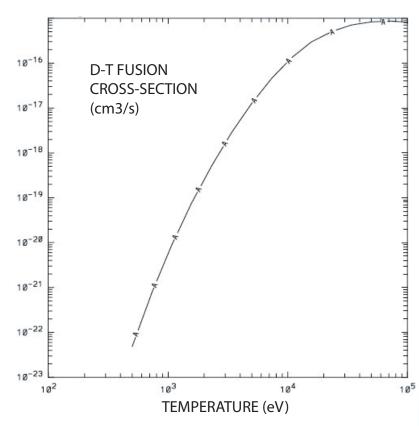

• For thermonuclear fusion, the reaction rate is given by a Maxwellian averaged cross section:

$$\frac{dn_1}{dt} = \frac{dn_2}{dt} = -\overline{\sigma v} n_1 n_2, \quad n_1, n_2 = \text{\# particles/cm}^3$$

 D-T is the preferred fuel because of its higher cross-section

$$n_D = n_T = \frac{n_i}{2}, \qquad \frac{dn_i}{dt} = -\frac{\overline{\sigma v} n_i^2}{2}, \qquad n_i = \text{# ions/cm}^3$$

 To reach a value of even 1% of peak, a temperature of 4 keV (50,000,000 deg. K) must be reached and sustained.

The rate equation can be integrated to give expressions for the number density and fusion energy produced as functions of time.

• Number density:
$$\frac{dn_i}{n_i^2} = -\frac{\overline{\sigma v}}{2}dt$$
, $\frac{\overline{\sigma v}}{2}t = \frac{1}{n_i} - \frac{1}{n_o}$, $n_i = \frac{n_o}{1 + \frac{\overline{\sigma v}}{2}n_o t}$

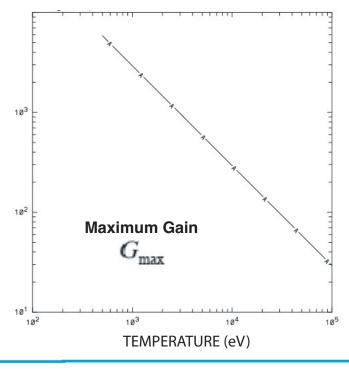

• Energy produced:
$$E_{FUS} = \varepsilon_{FUS} \frac{n_o - n_i}{2} = \varepsilon_{FUS} n_o^2 t \frac{\overline{\sigma v}}{4} \frac{1}{1 + \frac{\overline{\sigma v}}{2} n_o t}$$
, $\varepsilon_{FUS} = 17.6 \text{ MeV}$

$$\dot{Q}_{FUS} = \frac{dE_{FUS}}{dt} = -\frac{\varepsilon_{FUS}}{2} \frac{dn_i}{dt} = \varepsilon_{FUS} n_i^2 \frac{\overline{\sigma v}}{4}$$

- Initial plasma energy: $3n_o T_o$
- Gain:

$$G = \frac{E_{FUS}}{3n_o T_o} = G_{\text{max}} n_o t \frac{\overline{\sigma v}}{2} \frac{1}{1 + \frac{\overline{\sigma v}}{2} n_o t}, \qquad G_{\text{max}} = \frac{\varepsilon_{FUS}}{6T_o}$$

• G depends only on $n_a t$, tells how long plasma must be "confined"

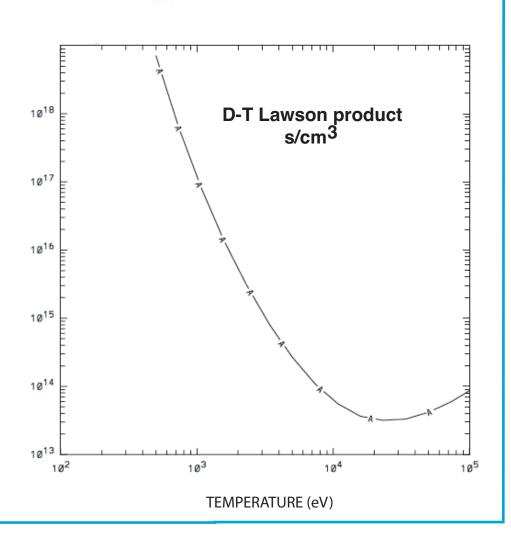

"Scientific breakeven" (G=1) is a continuing goal of fusion research

• G=1 when
$$n_o t = \frac{2}{\overline{\sigma v}} \frac{1}{G_{\text{max}} - 1} = L$$
, $L = \text{Lawson product}$

 Plasma must be confined for the "Lawson time" to achieve scientific breakeven:

$$\tau_L = \frac{1}{n_o} \frac{2}{\overline{\sigma v}} \frac{1}{G_{\text{max}} - 1} \approx \frac{2}{n_o \overline{\sigma v} G_{\text{max}}}$$

Unfortunately, plasma energy loss to cold surroundings by thermal conduction and radiation is a major obstacle to fusion

Losses reduce the effective gain:

If
$$\dot{Q}_{loss} = \phi \dot{Q}_{FUS}$$
, $G_l = \frac{E_{FUS} - E_{loss}}{3n_o T_o} = (1 - \phi) \frac{E_{FUS}}{3n_o T_o} = (1 - \phi)G$, $(G_l)_{max} = (1 - \phi)G_{max}$

Losses also increase the time to achieve breakeven:

$$G_l = 1 \text{ when } t = \frac{1}{n_o} \frac{2}{\overline{\sigma v}} \frac{1}{(G_l)_{\text{max}} - 1} = \tau_L \frac{G_{\text{max}} - 1}{(G_l)_{\text{max}} - 1} \approx \tau_L \frac{1}{1 - \phi} = N\tau_L$$

$$\dot{Q}_{FUS}$$
 / \dot{Q}_{loss} 1 1.1 1.25 2 5 10 ϕ 1 0.9 0.8 0.5 0.2 0.1 N infinity 10 5 2 1.25 1.11

- Losses also mean heating equal to \dot{Q}_{loss} is required to sustain plasma.
- Useful energy production requires G > 1, i.e, confinement for many "Lawson times"-- $t = XN\tau_L$ for G = X, e.g., G = 10 requires t = 20 τ_L if $\varphi = 0.5$.

Comparing loss rates with fusion rates identifies the density-temperature space where fusion gain can be achieved

•
$$\dot{Q}_{loss} = \dot{Q}_{TC} + \dot{Q}_{RAD}$$
 $\dot{Q}_{RAD} = C_{RAD} n_i^2 T^{1/2}$ (Bremsstrahlung) $\dot{Q}_{TC} = -\nabla \cdot (K \nabla T)$ ($K = \text{thermal conductivity}$)

Radiation losses determine a minimum temperature:

$$\frac{\dot{Q}_{FUS}}{\dot{Q}_{RAD}} = \frac{\varepsilon_{FUS} n_i^2 \frac{\overline{\sigma v}}{4}}{C_{RAD} n_i^2 T^{1/2}} = \frac{\varepsilon_{FUS} \frac{\overline{\sigma v}}{4}}{C_{RAD} T^{1/2}}, \quad \text{independent of } n_i \qquad \frac{\dot{Q}_{FUS}}{\dot{Q}_{RAD}} \ge 1 \quad \text{when } T > 3 \; keV$$

• \dot{Q}_{TC} , ∇T must be approximated:

$$\dot{Q}_{TC} \approx -\frac{1}{V} \int \nabla \cdot (K \nabla T) dV = -\frac{1}{V} \oint_{S} K \nabla T \cdot d\overline{S} \approx -\frac{S}{V} K \nabla T \approx \frac{KT}{\gamma \alpha a^{2}}$$

$$a = \text{characteristic dimension}, \quad V = \varepsilon a^{3}, \quad \frac{V}{S} = \gamma a, \quad \nabla T \approx -\frac{T}{\alpha a}$$

- ε , γ are geometric quantities, i.e., for spheres ε =4 π /3, γ =1/3; simulations show 0.1 < α < 0.5; this paper uses α = 0.25.
- Loss rates depend upon ni, T, a, model for K=Ki+Ke, geometry (ε, γ) , profile details (α) , and, possibly, magnetic field B (through K).

The conduction rate can be used to determine the minimum system size and other relevant parameters for a desired loss ratio ϕ .

•
$$a_{\min}^2 = \frac{KT}{\gamma \alpha} \frac{1}{\phi E_{FUS} - E_{RAD}},$$

 $a_{\min} = a_{\min}(n_i, T, B)$

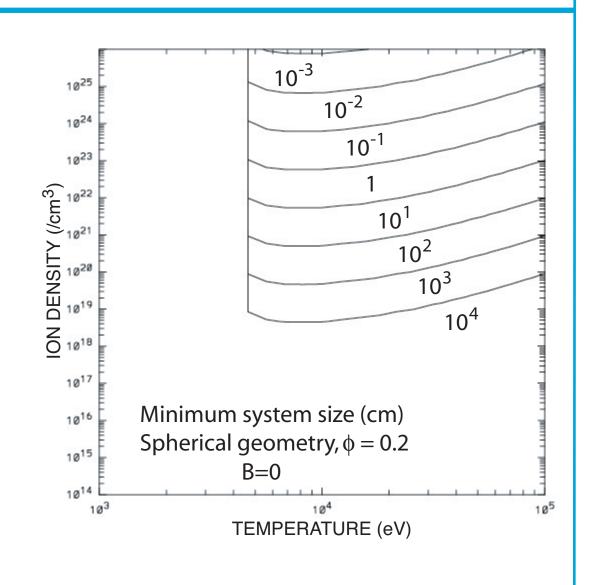

$$M = n_i(m_i + m_e)\varepsilon a_{\min}^3$$

•
$$E_{PLAS} = 3n_i T \varepsilon a_{\min}^3$$

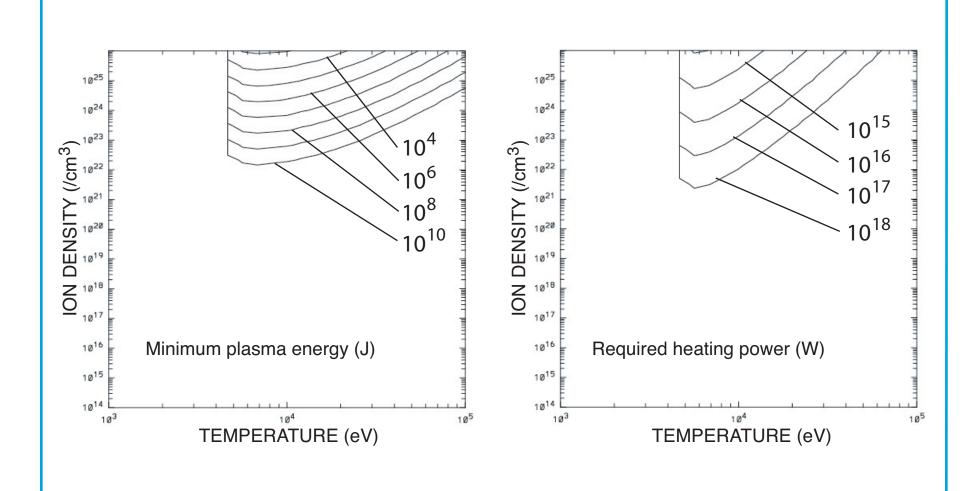

•
$$P_{HEAT} = (\dot{Q}_{TC} + \dot{Q}_{RAD}) \varepsilon a_{\min}^3$$

$$I_{HEAT} = \frac{P_{HEAT}}{S}$$

• If heating by compression, req'd velocity: $V_{\text{TMP}} = \frac{I_{\text{HEAT}}}{V_{\text{TMP}}}$

The mass, energy, and power requirements for unmagnetized (B=0) fuel are prohibitive except at very high density, pressure (>1e10 atm).

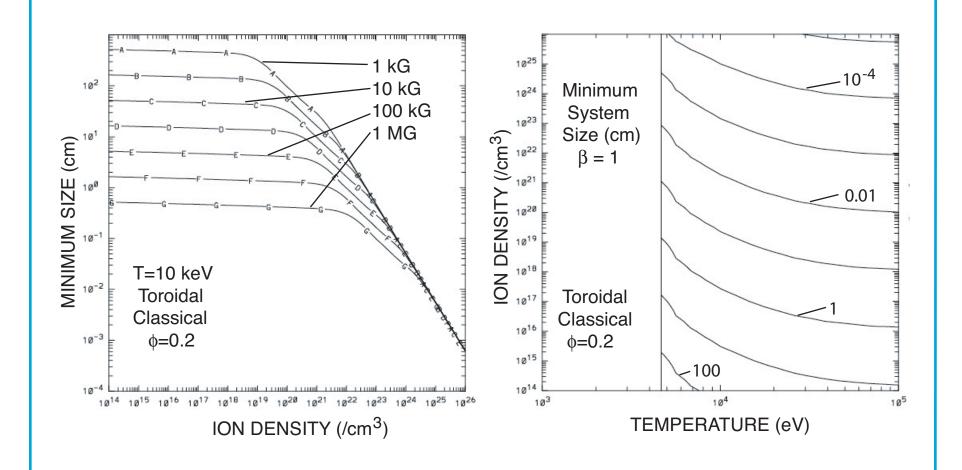

Electron thermal conductivity establishes the density lower limit; the dominant role of thermal conductivity was recognized early.

• Reference: Enrico Fermi, "Super Lecture No. 5--Thermal Conduction as Affected by a Magnetic Field," Los Alamos Report 344, Sept. 17, 1945.

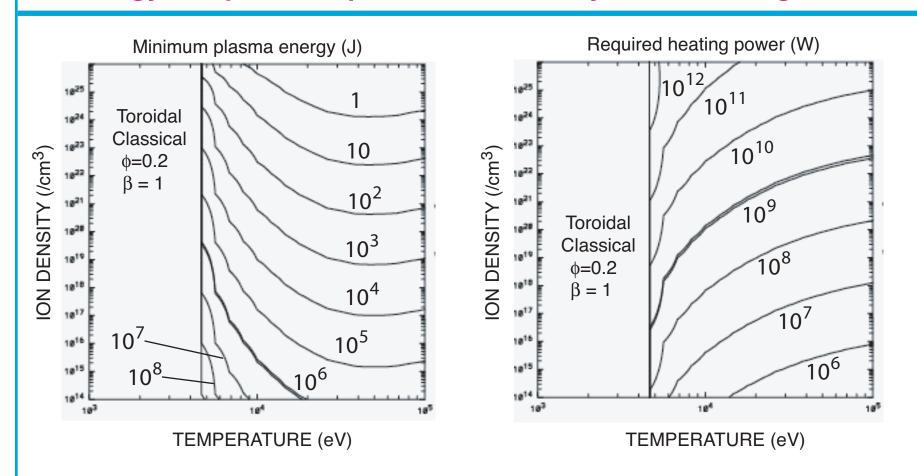

"A posible method of cutting down the conduction to the walls would be the application of a strong magnetic field, H. This tends to make the electrons go in circles between collisions, so impedes their mobility. Actually, it makes them go in spirals, and does not reduce the conductivity parallel to H but only to the other two dimensions, so one would probably want to design the container elongated in the direction of H, or even toroidal...with the lines of force never leaving the deuterium...rather large fields will be required...thus a field in excess of 20,000 gausses would help reduce conduction loss. While it would not be possible to produce such fields in a large volume in a steady state, the technical problem of making the field is much aided by the fact that the time during which the field is needed is much shorter than the usual relaxation time of magnetic fields, so it need be applied only instantaneously."

A magnetic field can significantly reduce the size of the burning plasma.

Note: β =plasma pressure/magnetic pressure

At every temperature/density point, magnetization of the fuel reduces the energy and power requirements, often by orders of magnitude.

 In contrast to unmagnetized fuel, the required heating power decreases with decreasing density. A priori, this might be expected to have a significant impact on cost.

FUSION 501--what they should have taught us in first-year graduate school.

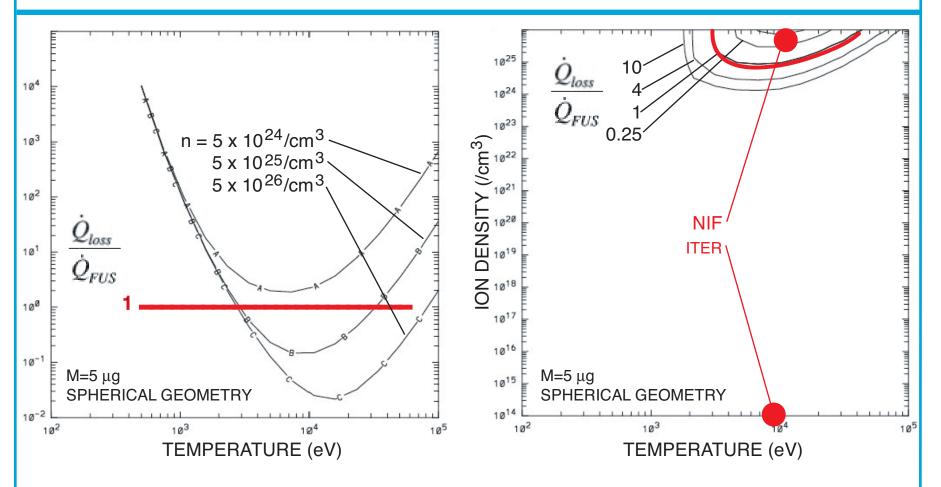

- What regions in parameter space do NIF and ITER access?
- Is it possible/feasible to consider other regions in parameter space?
- Can existing facilities be used to access other regions?
- Is there anything in between the extremes of Magnetic Confinement Fusion (MCF) and Inertial Confinment Fusion (ICF)?
- What would be the cost of a facility to access an intermediate region?
- Is it possible that fusion could be obtained at low cost?

Using published parameters (ni, T, B) and size (a or M), the loss rate expressions show extreme differences between NIF and ITER.

- To apply the simple expressions to NIF and ITER, we note the following:
 - the "hot spot" conditions (ni, T, mass) prior to ignition (self-heating by alpha particles) is somewhat ambiguous (ice evaporation).
 - the large toroidal field in tokamaks (50 kG in ITER) provides stability only, does not reduce thermal conduction.
 - thermal losses based upon the tokamak poloidal field (10 kG in ITER) are 30 X classical.
 - if losses had been classical, breakeven could have been achieved in a TFTR-class machine

	n om2	T	a	M	Eplas	Pheat	lheat	¢
	cm3	keV	cm	g	J	W	W/cm2	loss ratio
NIF	5e25	10	2.8e-3	20e-6	23e3	1.3e15	1.3e19	0.07
ITER min. tok.	1e14	8.4	230	0.3	300e6	157e6	25	0.45
classical	1e14	8.4	66	7e-3	6.8e6	1.6e6	3.2	0.2

For unmagnetized fuel (e.g., ICF), fusion energy production rate exceeds loss rate (i.e., $\dot{Q}_{FUS} \ge \dot{Q}_{loss}$) only at very high density

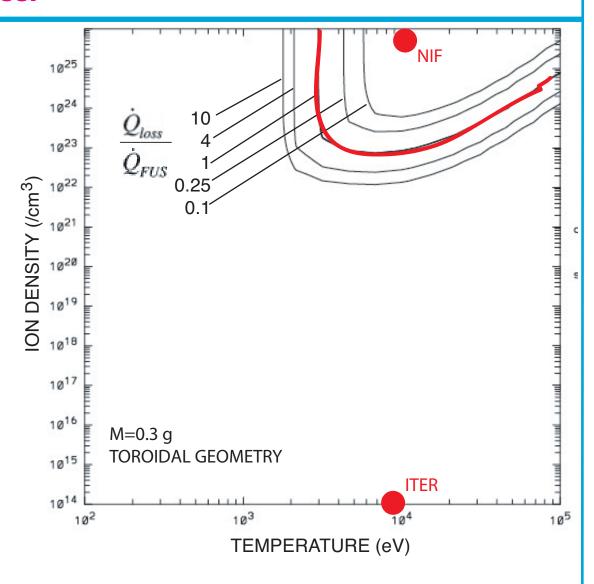

• The NIF "hot spot" (M ~ 5 μ g, n ~ 5 x 10 25 /cm³, t ~ 10 keV) reaches a point where $\dot{Q}_{loss}/\dot{Q}_{FUS}$ ~ 0.1 when the ignition rapid rise in temperature occurs due to alpha particle deposition.

The limited operating space for unmagnetized fuel is not strongly sensitive to the fuel mass.

 Increased mass reduces the effect of thermal conduction.

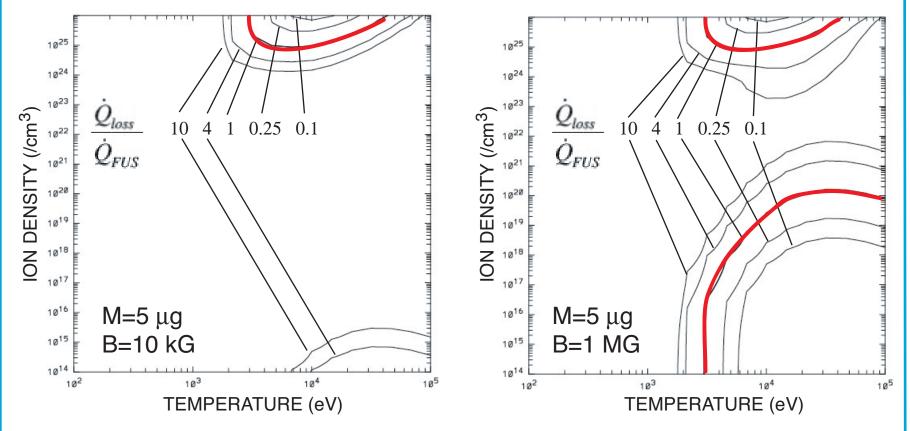

$$\dot{Q}_{TC} \approx \frac{KT}{\gamma\alpha} \left(\frac{\varepsilon n_i (m_i + m_e)}{M}\right)^{2/3}$$

 Even for the fuel mass of ITER (~ 0.3 g), unmagnetized fuel must operate at high density

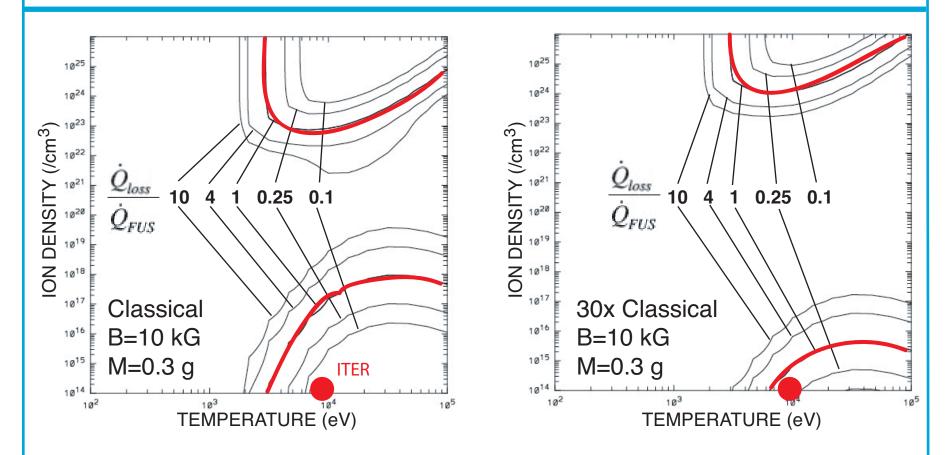

A magnetic field reduces the thermal conductivity across the magnetic field by $\sim 1+(\omega\tau)^2$.

• Even for the NIF hot spot mass ($\sim 5 \mu g$), a field of 10 kG opens up a low-density "island" where $\dot{Q}_{FUS} \ge \dot{Q}_{lost}$

 For 1 MG, there is almost a continuum between the usual MCF and ICF space.

ITER uses a poloidal field of ~ 10 KG to limit conduction losses; tokamak data suggests that transport is 30 x classical

• The 30x increase means that ITER operates in a range where losses are 0.35 x fusion, instead of only 0.03, i.e., ϕ =0.35.

Knowing the cost of ITER and NIF, the cost of fusion facilities in any region of parameter space can be estimated.

$$Cost = c_1 E_{PLAS} + c_2 P_{HEAT} \approx \frac{\$10B}{E_{ITER}} E_{PLAS} + \frac{\$3B}{P_{NIF}} P_{HEAT}$$

$$Facility Cost(\$)$$

• The reduced size/energy (when compared to ITER) and reduced power (when compared to NIF) lead to a very much lower cost at an intermediate density using magnetized fuel.

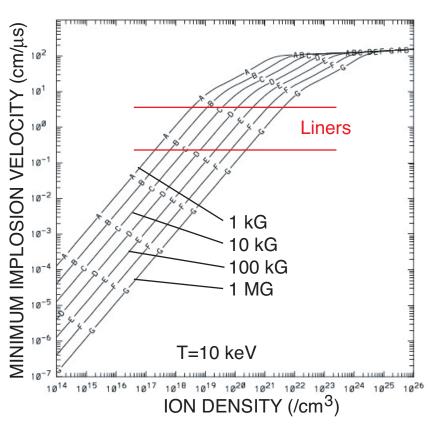

For magnetized fuel, the reduced size/energy and reduced power in the intermediate density region lead to lower cost, even if 30x classical or Bohm transport is encountered.

Bohm transport would make the cost prohibitive at ITER density.

If very efficient compressional heating, as in ICF, is used to access the intermediate region, the required energy and implosion velocity is in the range already demonstrated by liners driven by modern high-current pulsed power machines (Atlas, Shiva-Star) and modern flux compression generators (DEMG).

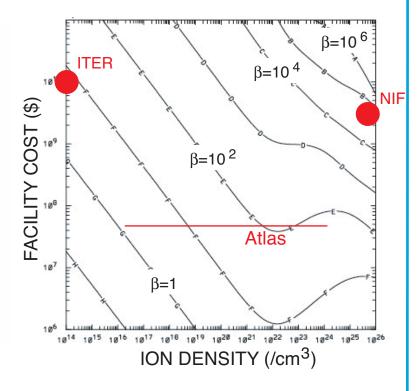

The Atlas capacitor bank (23 MJ, 30 MA, 6 μ s) at NTS was designed to drive imploding liners in the range of 1-10 MJ, 0.1-1 cm/ μ s to create high energy density environments.

 Atlas is, serendipitously, an ideal machine for accessing the intermediate density regime by compressing magnetized fuel with a magnetically driven liner.

Atlas' cost of \$50M confirms the simple cost estimates for fusion facilities.

Modern imploding liner technology opens a new pathway to fusion: Magnetized Target Fusion (MTF)

- MTF operates in the unexplored density space between MCF and ICF.
- The space is accessed by liner compression of magnetized plasma.
- Assume adiabatic compression, flux conservation:

Quasi-spherical
$$\frac{n}{n_o} = \left(\frac{r_o}{r}\right)^3$$
 $\frac{T}{T_o} = \left(\frac{r_o}{r}\right)^2$ $\frac{B}{B_o} = \left(\frac{r_o}{r}\right)^2$ $\frac{\beta}{\beta_o} = \frac{r_o}{r}$ $\frac{\omega \tau}{(\omega \tau)_o} = \left(\frac{r_o}{r}\right)^2$ Cylindrical $\frac{n}{n_o} = \left(\frac{r_o}{r}\right)^2$ $\frac{T}{T_o} = \left(\frac{r_o}{r}\right)^{4/3}$ $\frac{B}{B_o} = \frac{r_o}{r}$ $\frac{\beta}{\beta_o} = \left(\frac{r_o}{r}\right)^{4/3}$ $\frac{\omega \tau}{(\omega \tau)_o} = \frac{r_o}{r}$

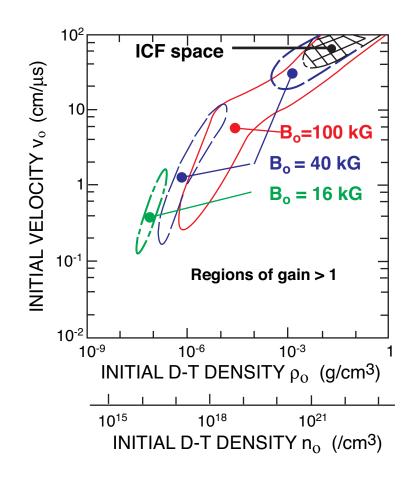

To limit ro/r=10, but reach n=1e20/cm3, T=10 keV, B=1 MG:

Quasi-spherical--initial n, T, B = 1e17/cm3, 100 eV, 10 kG

Cylindrical--initial n, T, B =1e18/cm3, 464 eV, 100 kG

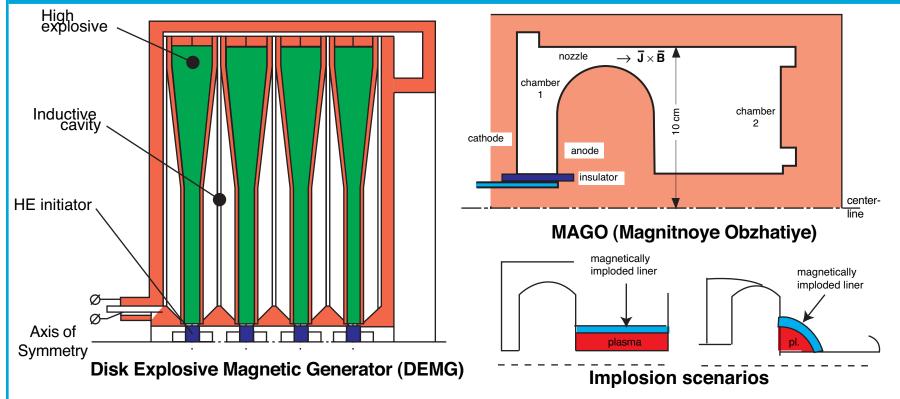

- In MTF, there is a trade-off between convergence ro/r and initial n, T, B.
- MTF does not need the high convergence (r₀/r ~ 30) that makes ICF difficult.

To fully determine the initial parameters (or final conditions), detailed implosion computations are needed.

- Lindemuth and Kirkpatrick (Nuc. Fus. 23, p. 263, 1983) formulated a simple implosion model and found a surprisingly broad parameter space.
- The results were confirmed by LASNEX and other computations.
- The simple model continues to serve as a guide for more detailed, multidimensional MHD computations.
- At the time the model was formulated, lasers were considered the most likely drivers, and plasma creation was considered a challenge (so use implosion E=10 kJ, T₀=50 eV).

Since the L-K model, advances in drivers and plasma formation allow consideration of more energetic implosions (e.g., 20 MJ) and higher plasma density and temperature (e.g., 1e18/cm3, 300 eV)

 DEMG and MAGO systems developed by the All-Russian Institute of Experimental Physics (VNIIEF) have catalyzed a growing international interest in MTF, e.g., Los Alamos National Lab. (LANL), Air Force Research Lab. (AFRL), India Institute for Plasma Research (IPR), and the University of Nevada-Reno (UNR).

MTF is <u>not</u> magnetic confinement (e.g., MFE); MTF is <u>not</u> polarized fuel

- Simple field topologies → easier plasma creation
- Shorter lifetime required
- Wall contact tolerable, maybe desirable
- $\omega \tau$ » 1 \rightarrow magnetic thermal insulation
- if β » 1 \rightarrow reduced instabilities
- if β » 1 \rightarrow little work compressing B
- Polarized fuel: $\sigma v \rightarrow 1.5 \ \sigma v$, relatively little effect

MTF is not merely the addition of a magnetic field to a "conventional" ICF Target--it is the complete rethinking of the compressional heating approach.

- B_o → approximately adiabatic compression (no shocks)
- Low $\rho \rightarrow$ bigger targets, reduced radiation rates
- T₀ → reduced radial convergence (e.g., < 10)
- Low v → less power, intensity
- ullet Less power, intensity o more, and less expensive, energy possible
- Big targets, low v → more massive pushers
- Massive pushers → long dwell, burn times
- Low v → adiabatic → no pulse shaping
- $\stackrel{-}{f B}
 ightarrow {
 m rB}$, not hor, for alpha deposition
- T_o, B_o \rightarrow fuel prep. prior to implosion
- Low ρ with B \rightarrow new physics regimes

CONCLUDING REMARKS--an unexplored fusion parameter space may mean fusion could yet be possible at low cost.

- MTF is a research topic, has not yet been demonstrated to provide substantial fusion yield. Although some physics uncertainties exist, no insurmountable obstacles have been identified.
- MTF is an "orthogonal," complementary alternate to MFE and ICF.
 Required technology (Atlas and/or DEMGs) exists for demonstration--no major capital investment in new facilities.
- Because MTF is qualitatively different from inertial or magnetic confinement fusion--different time, length, and density scales--MTF reactors will have different characteristics and trade-offs, increasing the chances that a practical fusion power scheme can be found.
- "The fusion fire--which men have contemplated in awe since they first raised their eyes to the stars--but first brought to Earth in our age, will clearly propel man beyond his Solar nursery, and forever foster and energize his terrestrial and cosmic endeavors. We may speak today of fusion fire as Aeschylus, the ancient Athenian poet, said of Prometheus' gift to mortals of the chemical fire: it will prove the means to inconceivably mighty ends."
 - --L. Wood and J. Nuckolls, 1971.

Modeling of Shock Attenuation in the Electra Circulator Loop

B. Lu, C. Lascar, J. Dion, and S. Abdel-Khalik - IFE Strategic Planning Workshop - April 24-27, 2007

Problem Definition

- A shock wave is created following e-beam energy deposition in the laser gas.
- Shock is gradually attenuated as it propagates around the circulator loop prior to the next pulse.
- Density gradients in the laser cell caused by the shock "remnants" may impact beam quality.

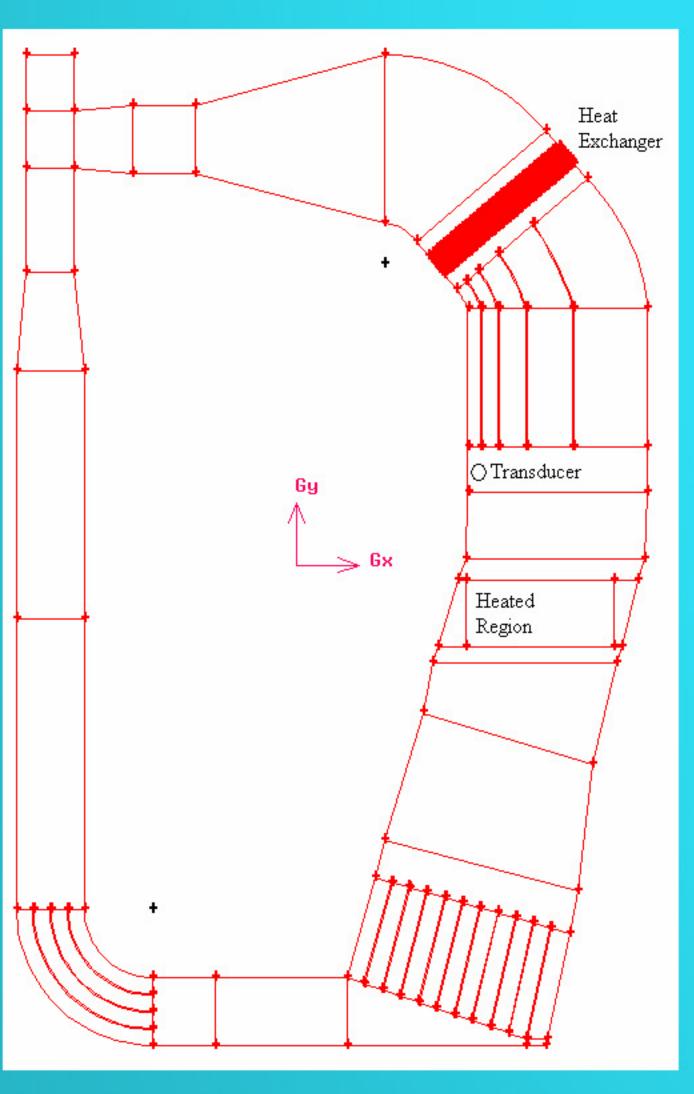

Objectives

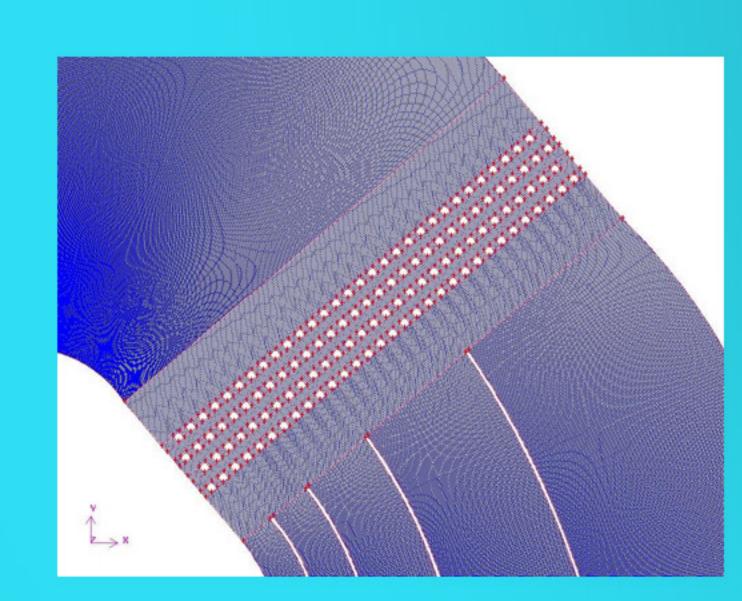

- Numerically simulate shock propagation and attenuation in the Electra main amplifier circulator loop following e-beam energy deposition in the laser gas.
- Quantify the extent of non-uniformity in the gas density prior to the next pulse for 5 Hz operation at prototypical gas conditions.
- Explore means by which the pressure wave can be further attenuated to achieve the desired uniformity in gas density for long-term (5 Hz) operation without significant increase in circulator power requirements.

<u>Approach</u>

- •Use FLUENT 6.2.16 to model gas heat-up by e-beam energy deposition (100 ns) and subsequent shock propagation and attenuation prior to the next shot (200 ms); multiple shots can be modeled.
- Initial studies used a simplified 2D loop to assess the code's suitability and examine effect of modeling options, geometry, and boundary conditions on shock attenuation.
- Current studies use actual Electra main amplifier circulator loop geometry and operating conditions.
- Results obtained for 2D simplified analyses.
- Calculations using actual 3D geometry are in progress.

Electra Circulator 2D Loop Nodalization

No. of mesh points (2D model): 847,648

Initial Conditions:

- Loop contains stagnant argon.
- Initial pressure = 1.5 atm (152 kPa).
- Initial temperature = 300 K.

Boundary Conditions:

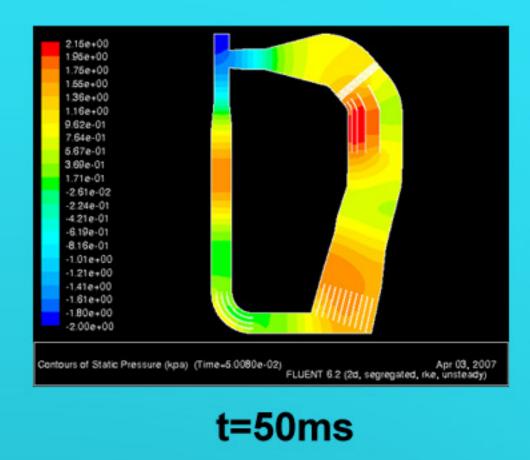

- Adiabatic loop walls.
- No slip boundary walls and straightener surfaces.
- "Smooth" surface.

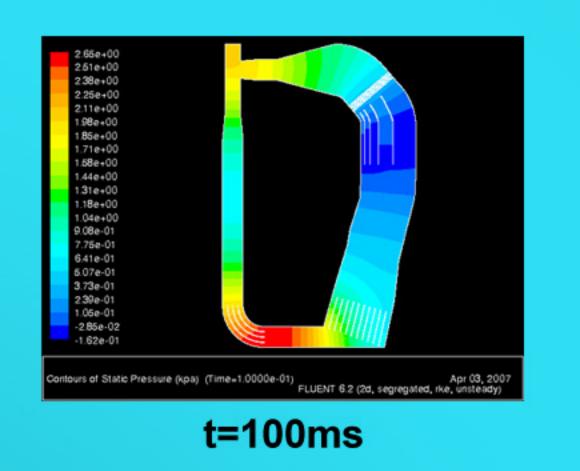

<u>Assumptions</u>

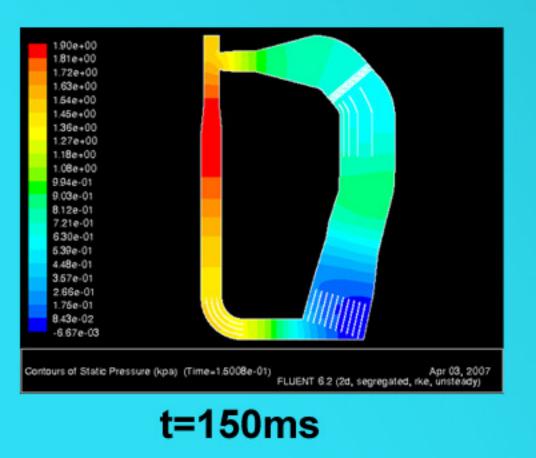

- Argon is assumed to be a compressible ideal gas with constant Cp, k, and μ.
- Source term/energy generation rate during the 100 ns heating period selected to produce the same temperature rise as that produced by the electron beams' deposition (~ 50 K).

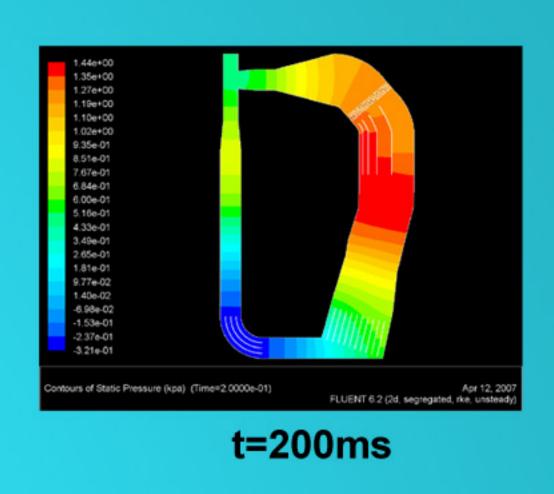

Pressure Contours in the 2D Loop after 100ns of Heating

Simplified Loop Geometry and Results for Parametric Studies after 400 ms (2 pulses)

8 m Fan ensuring circulation 3 m Pulsed Heating of a 30 cm-long section (100 ns pulse width) 0.5 m

Effects of Surface Roughness

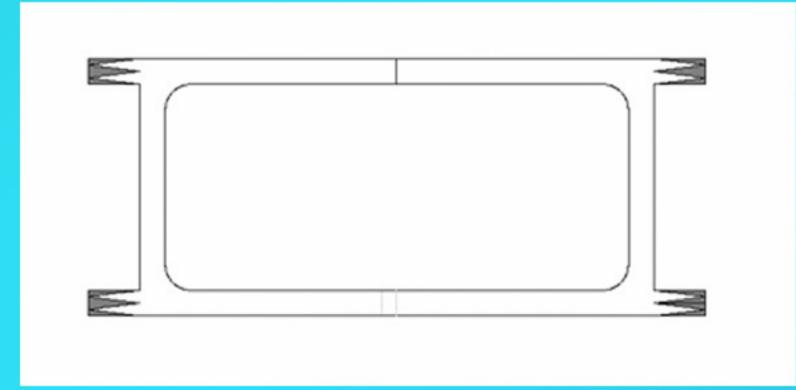

- Previous simulations assumed a smooth surface corresponding to roughness height = 0 mm.
- Slight effect (1%) on shock attenuation when roughness height is increased up to 4 mm.

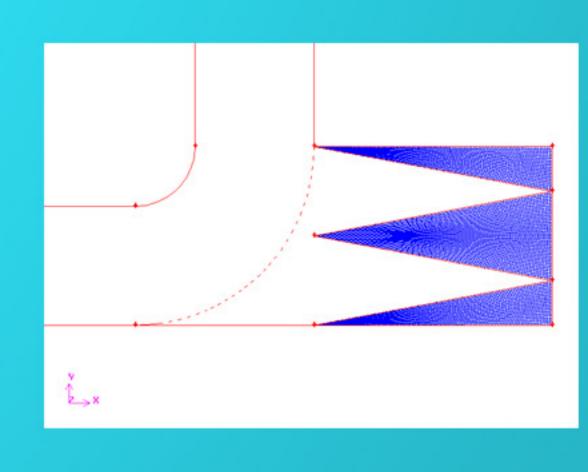

Effects of Convection Heat Loss

- Previous simulations performed assuming adiabatic boundaries.
- New simulation, heat transfer coefficient = 20 W/m².K.
- Slight effect (<1%) on shock attenuation.

Porous Absorber Cones

- Can significantly attenuate shock with modest increase in loop pressure drop.
- Parametric studies indicate that optimum porosity ≈ 60%.

<u>Conclusions</u>

- Shock propagation and attenuation can be modeled using FLUENT.
- Model needs to be extended to simulate actual 3D geometry with flow "obstructions" at prototypical flow conditions.
- Code results for pressure/frequency at instrumented locations should be experimentally validated prior to hardware modification.

G. W. Woodruff School of Mechanical Engineering, Atlanta, GA 30332-0405 USA

Accelerated Plasma Blocks Driven by Petawatt-Picosecond Laser Pulses for Igniting Near Solid Density DT

George H Miley¹ and Heinrich Hora²
¹U of Illinois, Urbana, IL 61801,USA
²U of New South Wales, Sydney,
2052, Australia

Outline

- Review of prior volume ignition studies.
- Badziak effect and non-linear ion acceleration.
- Plasma block acceleration as an alternative to fast igniter electron beam ignition.
- Fusion regime involving 10-kJ input to produce 100 MJs or more output.

• • • Introduction

- 30 years ago it was impossible to
 - ignite solid deuterium-tritium by pulsed laser irradiation
 - irradiation by ion beams had current densities of low magnitude
- This changed as improved drivers and targets were designed and the fast ignitor concept was introduced. However, very high compressions are still envisioned.
- Recently a method that avoids high compression was proposed based on an anomalous effect observed using PW-ps laser pulses

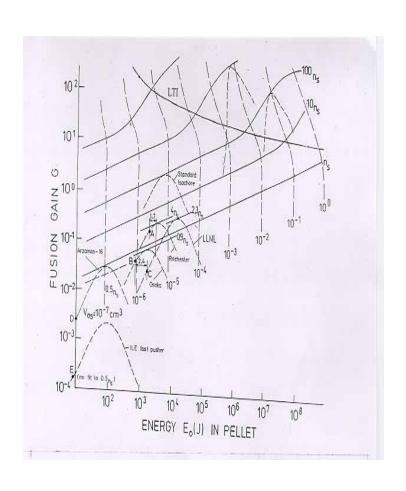

• • • Basis

- Both experiments and theory concludes that suppression of prepulses by a factor 10⁸ would
 - avoid relativistic self-focusing allowing broad area compression
 - gives directed 80-keV DT ion current densities in space- charge neutral plasma blocks of modest temperature. These blocks can reach parameters that allow them to produce fusion flame in the nearly uncompressed or solid DT target. The parameter that it can exceed are:
 - 10¹¹ Amps/cm²,
 - energy flux densities of 10⁸ J/cm²,
 - block thickness.
- Conditions for the energy flux are further relaxed by
 - considering interpenetration effects
 - the quantum modification of collisions
 - collective reduction of stopping power and double layer mechanisms

Review Of Prior Volume Ignition Studies

- Prior measurements at Rochester, Osaka, LLNL and Arzamas-16 agree with isotropic burn model.
- When radiation trapping and alpha reheat are included high gains occur with volume ignition above the threshold energy input.
- Optimized volume ignition requires high density and mass targets than does spark ignition, but is much simpler to implement.

Experiments Agree Well with Isentropic Burn Model

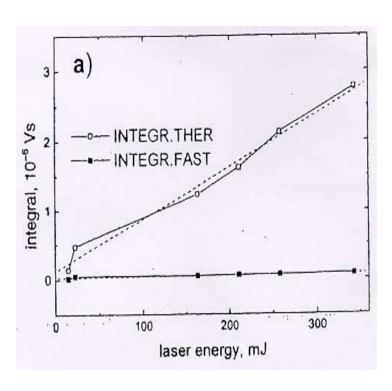

Optimized core G (full lines) for 3-D self-similar volume comp. and simple burn (G<8) (~ quenching:1995) and volume ignition for G>8 with low T ignition above LTE line. Measurement at Rochester (A), Osaka (*B*), LLNL (*C*) and Arzamas-16 (D) agree with isentropic volume burn model, while the earlier fast pusher (E) with strong shocks does not.

Badziak Effect & Non-Linear Ion Acceleration

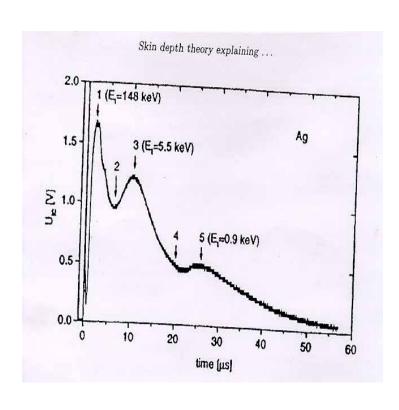

- 5 energy groups of lons observed for irradiation of a copper target during 1.2 ps Nd glass laser.
- Fast ions attributed to relativistic self focusing of laser beam.
- Slow ions characteristic of nonlinear force acceleration.
- Analysis suggests plasma block acceleration possible.

Badziak Effect Results In Large Number Of Fast & Thermal Ions

anomalous ion emission: No. of fast and thermal ions emitted from a copper target at Nd glass laser irradiation of (1.2 ps) focused to 30 wave length dia. with prepulse suppression of 108 for <0.1 ns before the main pulse.

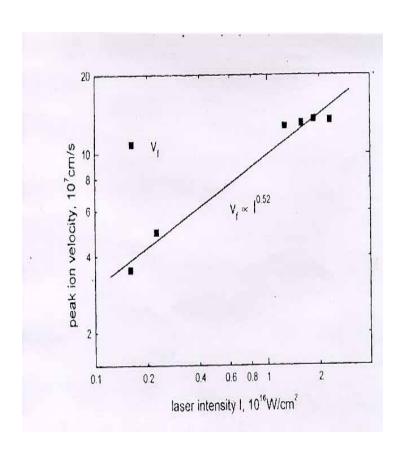

Ion Energy Groups Observed During Irradiation

o TOF signal from a flat ion collector with a silver target irradiated by an iodine second harmonic laser pulse of 14 J and 0.35 ns.

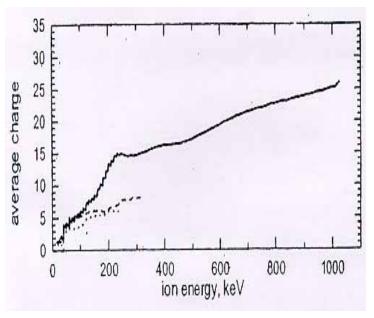

Three groups of ions appear! The fastest ions (1), the second fastest ions (3) and the slow thermal ions (5).

Fast Ion Velocity Scales As 10.52

 Velocity of the fast ions measured by TOF.

Shorter Laser Pulses Lead to a Lowering Of the Average Charge

 Same as prior Slide but 1.2 ps –0.7 J laser pulses.

Plasma Block Acceleration As an Alternative to Fast Igniter Electron Beam Ignition

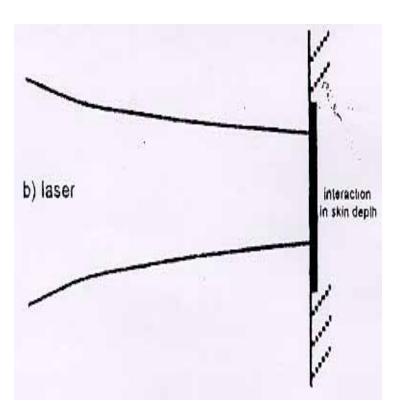

- Block acceleration requires pre-pulse suppression to prevent plasma self focusing.
- Using studies from light ion beam fusion volume ignition with a ion current of 10¹⁰ Amp/cm² from 10-kJ pulses, calculations predict high gain volume ignition is possible.

Pre-generated Plasma Causes Self-focusing

 Geometry for subsequent volume-forced nonlinear electron acceleration with separation by the ion charge Z. The pre-generated plasma before the target causes relativistic self focusing of the laser beam to less than a wave length dia. and very high acceleration due to the strong gradient of laser field density.

Elimination of Plasma Prevents Self-focusing

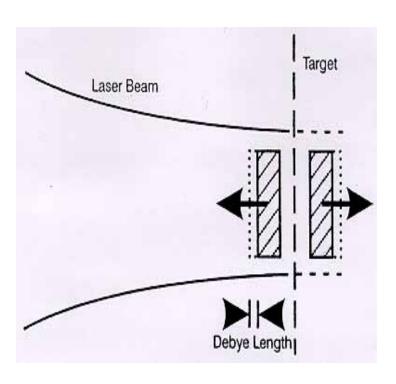

The very thin plasma does not produce self-focusing, hence lower ion energies.
 This ideal geometry has frequently been assumed in prior studies.

Nonlinear Force Effects Create High Electric Field Amplitudes

the electromagnetic energy density Nd glass laser 10¹⁶ W/cm² after n_e~ 5x10²⁰ cm⁻³ is reached at 12um from the surface. The maximum corresponds E~3.1 times higher than vacuum due to dielectric swelling.

Plasma Block Acceleration By Non-Linear Force

 Skin depth laser interaction: nonlinear force accelerates a plasma block against the laser light and another block towards the target interior. Election clouds form with a thickness of the effective Debye length.

Block Ignition Targets

- Design point-generation of reaction front with interpenetrating ion energies ~ 100 keV.
- Use high aspect ratio ps pulse defocused to large cross section.
- PW pulses with final intensity of few 10¹⁷
 W/cm² gives swelling of 2-3x.
- Resulting ion current density of 10¹⁰ Amp/cm^{2,} giving 10⁶ J/cm².

Ignition Criteria

- Collective interaction of ions determines stopping power.
- Ignition condition for fusion reaction wave reduces to minimum energy density E_{min} for DT of $E_{min} = 10^6 \text{J/cm}^2$.
- Reaction wave of high intensity ion beam of minimum current density j_{min} = 10¹⁰ A/cm².

• • • Conclusions

- This new approach overcomes the DT compression issues and electron beam issues of the fast ignitor
- Plasma block ignition, 10-kJ laser pulses produce 100-MJs of fusion energy
- Potential for simplified and lower cost energy production

Mitigation of helium-induced tungsten morphology change using the tamped target design*

G.A. Moses and T.A. Heltemes

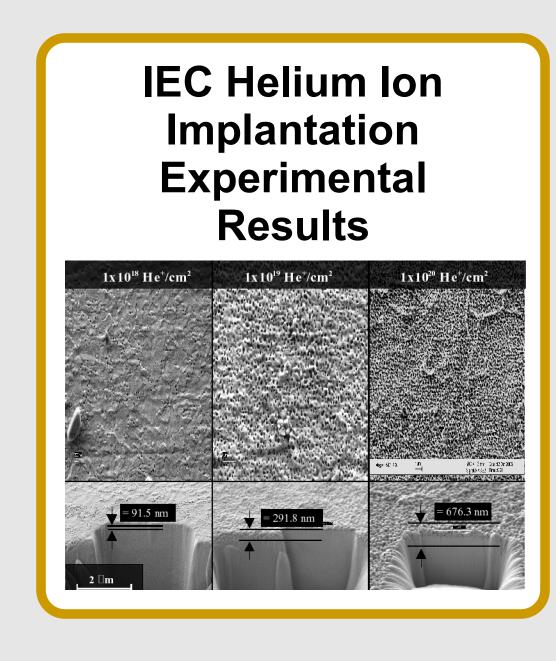

HAPL Chamber Problem

The reference HAPL chamber design consists of a 10.5 m radius chamber with an ambient temperature of 600 °C and a nominal background gas pressure of 0.5 mtorr. 365 MJ deuterium-tritium targets are imploded in the chamber at a rate of 5 Hz. Until recently, it was thought that the first wall and breeding blanket lifetime was limited by neutron damage. Recent experiments with low-energy helium ion bombardment performed by the University of Wisconsin – Madison Inertial Electrostatic Confinement (IEC) experimental group indicate significant erosion of the plasma-facing surface due to alpha particle implantation. The limiting factors of the armor and/or first wall lifetime now appear to be:

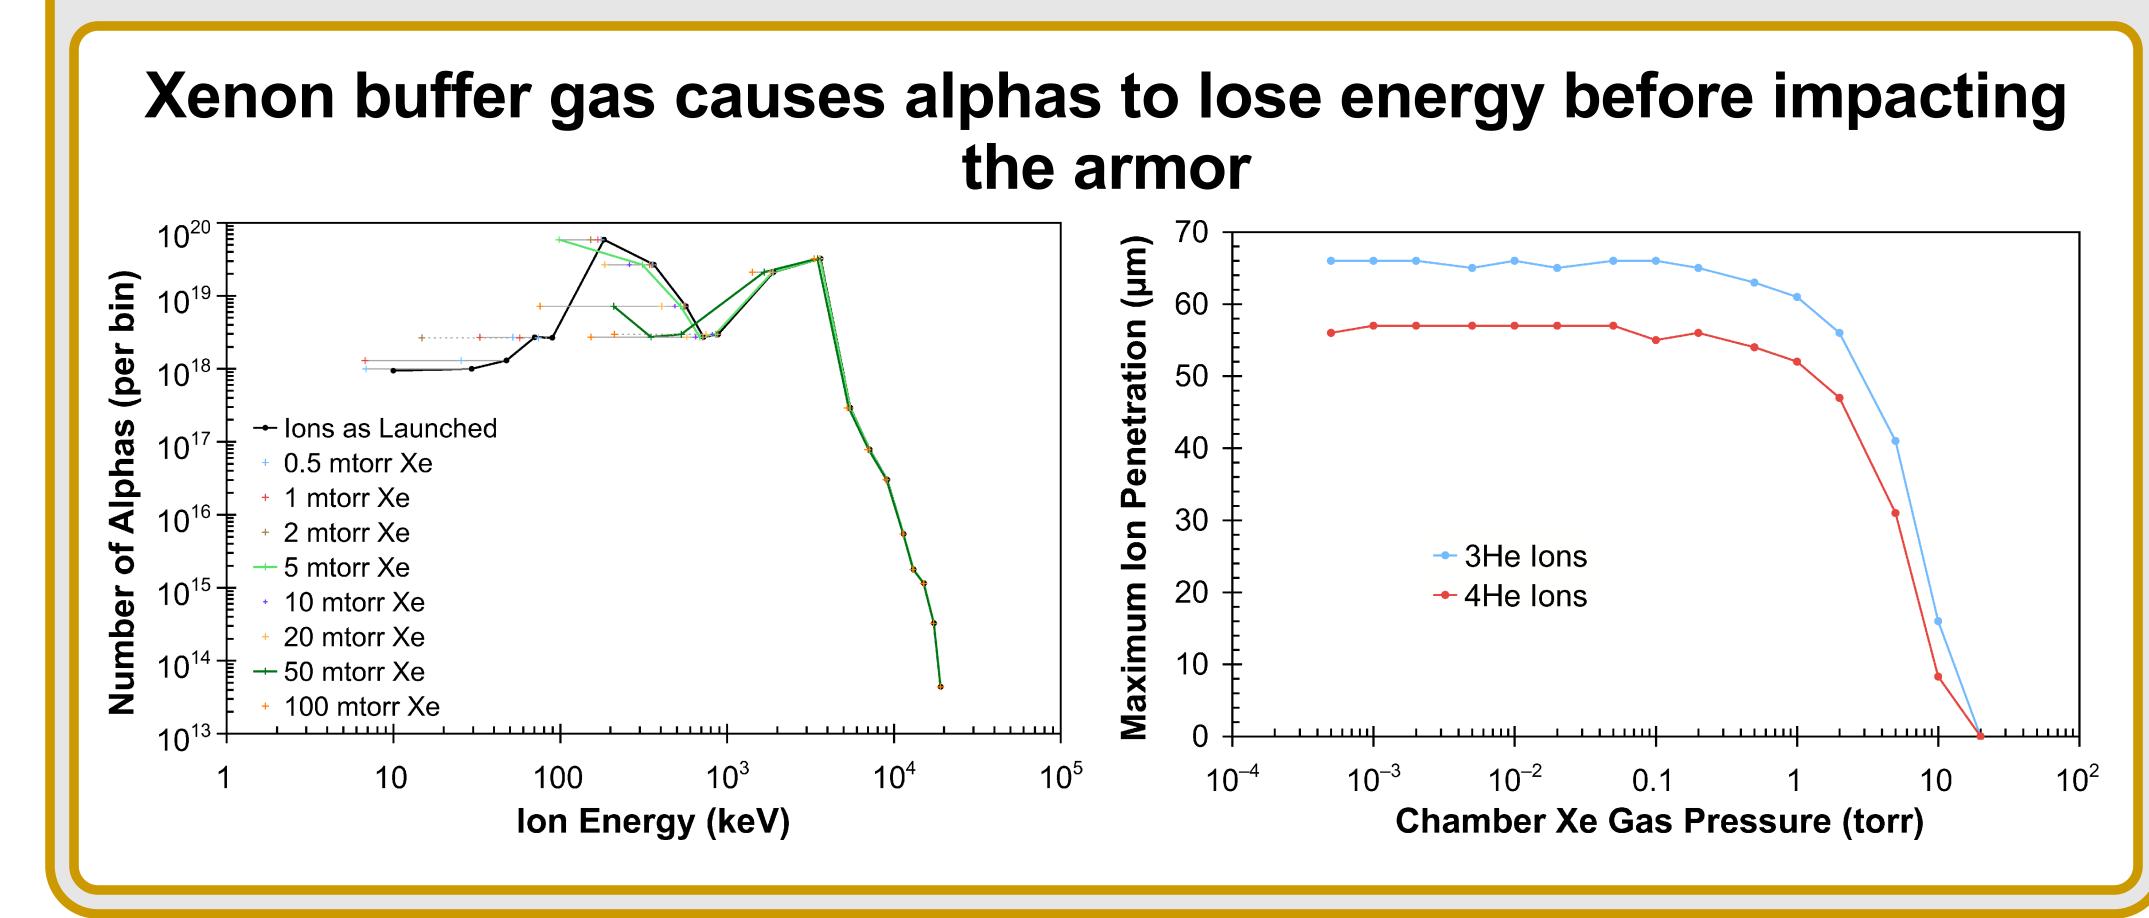

- 1. Neutron damage due to atomic displacements in the crystal structure (DPA lifetime).
- 2. Thermal stress due to rapid cyclical temperature rise.
- 3. Morphology change and armor erosion due to low-energy alpha implantation.
- 4. Armor erosion due to high-energy alpha accumulation in subsurface grain boundaries.

MCNP neutronics simulations show that the DPA lifetime of the first wall and blanket structures is approximately 3½ full-power years (FPY). The chamber radius was specified to be 10.5 m, based on thermal analysis that limits the temperature rise on any given target shot to 2400 °C with tungsten armor.

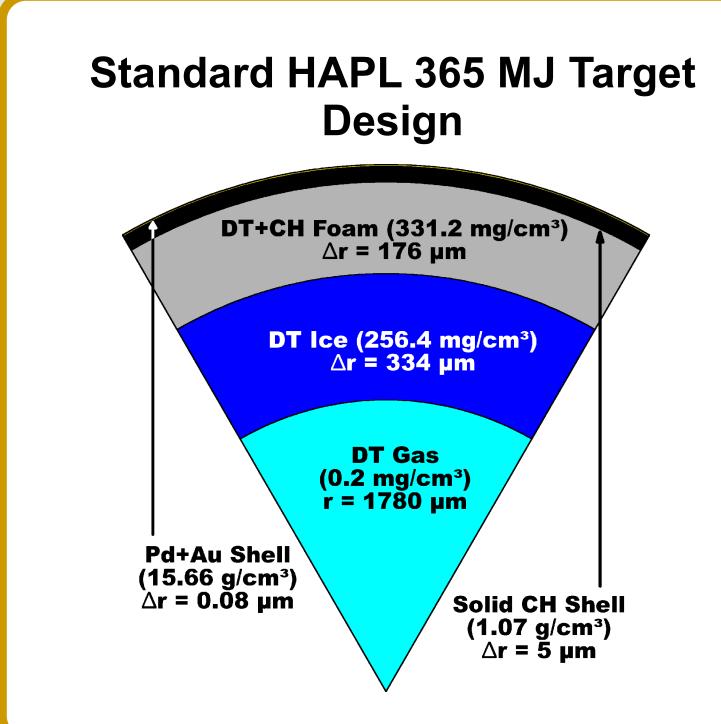

IEC experiments show that low-energy alpha implantation erodes the tungsten armor at rate of 1.1 μ m per 10¹⁹ ions/cm². The current HAPL chamber design is based on a 250 μ m layer of tungsten over a ferritic steel substrate. Based on the erosion rate from the IEC experiments and the alpha ion spectrum produced by simulations performed at Lawrence Livermore National Laboratory (LLNL), the tungsten armor will erode at a rate of 126 μ m/FPY. Thus, the tungsten armor will be completely eroded in just under 2 FPY, neglecting the damage done by the high-energy (above 600 keV) alpha particles.

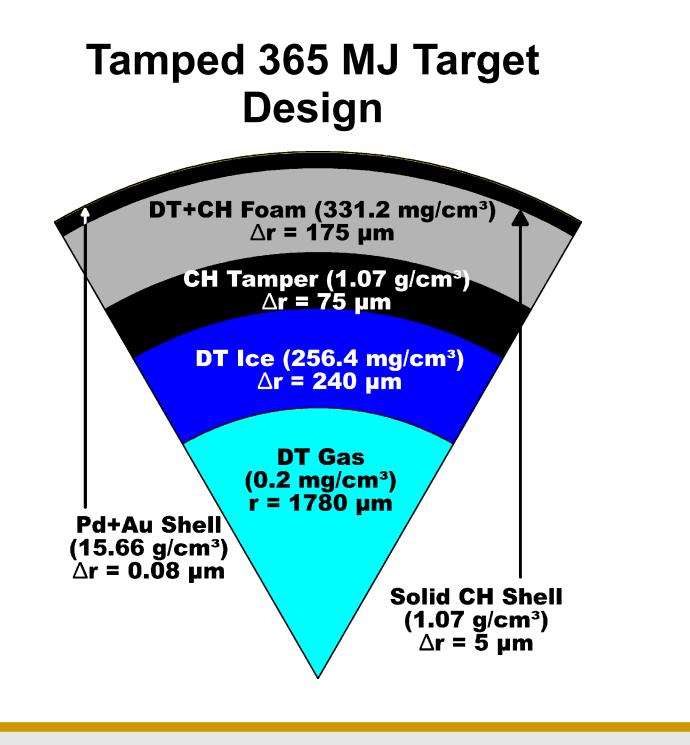

To prevent the low-energy alpha implantation from becoming the lifetime limiting damage mechanism, steps must be taken to prevent the low-energy alphas from reaching the armor. One can stop the ions by introducing a buffer gas. First we explored the possibility of stopping all alpha particles from reaching the armor by simply increasing the pressure of a xenon buffer gas. Our simulations indicated it would take an excessive amount of gas — on the order of 20 torr — to stop all alphas from impacting the armor. The amount of buffer gas required was determined to be unacceptable due to frictional target heating during injection into the chamber.

Tamped Target Solution

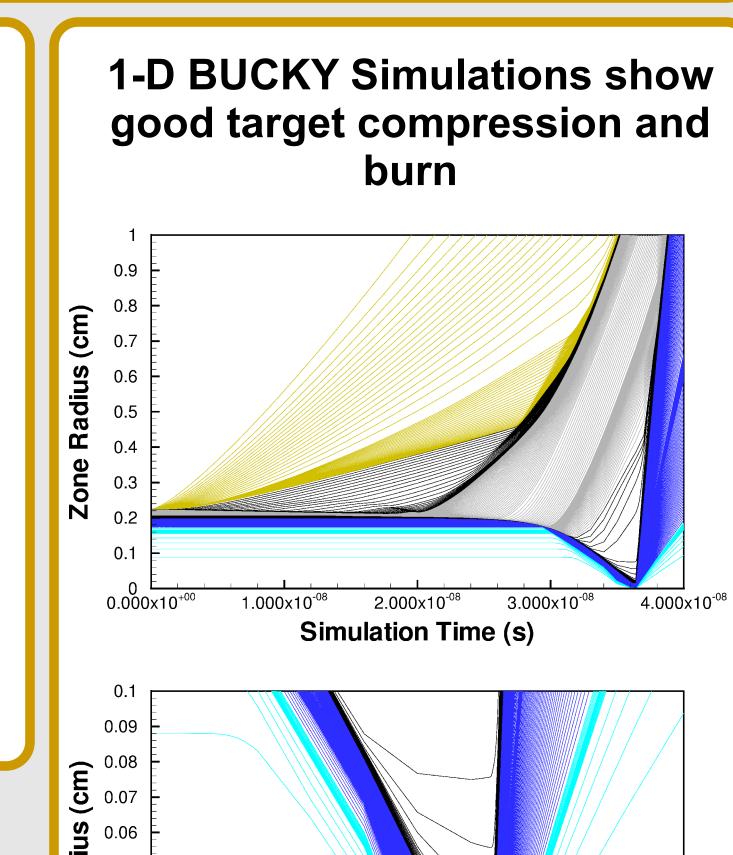

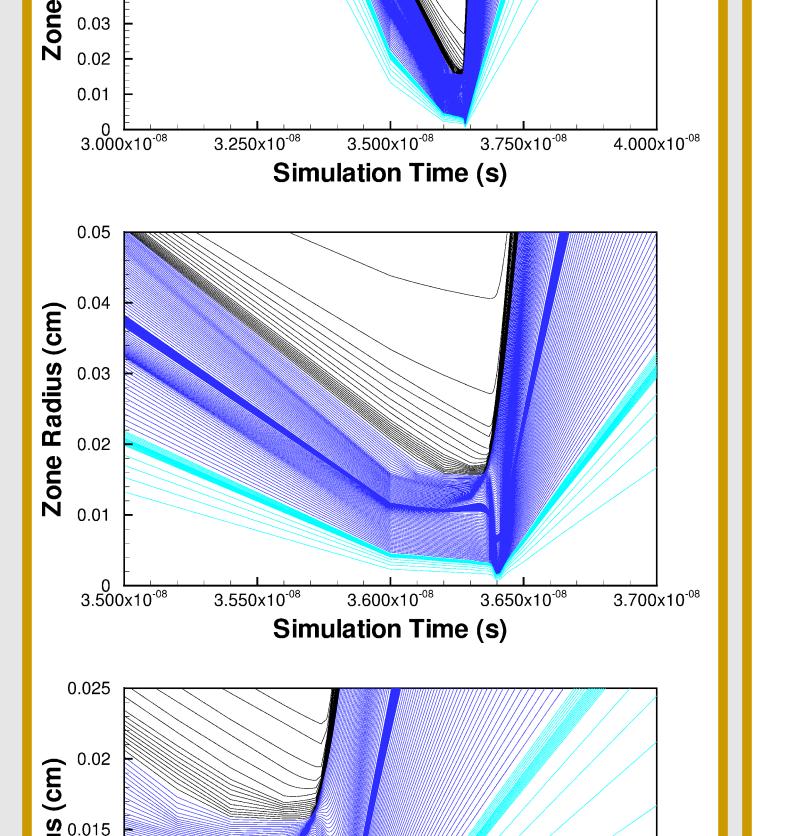

To prevent the alphas from reaching the tungsten armor, 0.35 g/cm² of areal density must lie between the burning DT plasma and the tungsten armor. This can be achieved via a high-pressure buffer gas (see previous panel) or the introduction of a tamper into the target design. The tamper is a material that lies in the compressed core of the target and reaches the appropriate ρR value of (0.35 g/cm²) during the fusion burn process.

For the purposes of this analysis, a 75 µm plastic tamper was added to the HAPL target between the DT ice and ice-wicked plastic foam layers. 1-D BUCKY simulations were performed that achieved a 364 MJ fusion yield using the same driver energy (2.4 MJ) and power profile as the original HAPL target design.

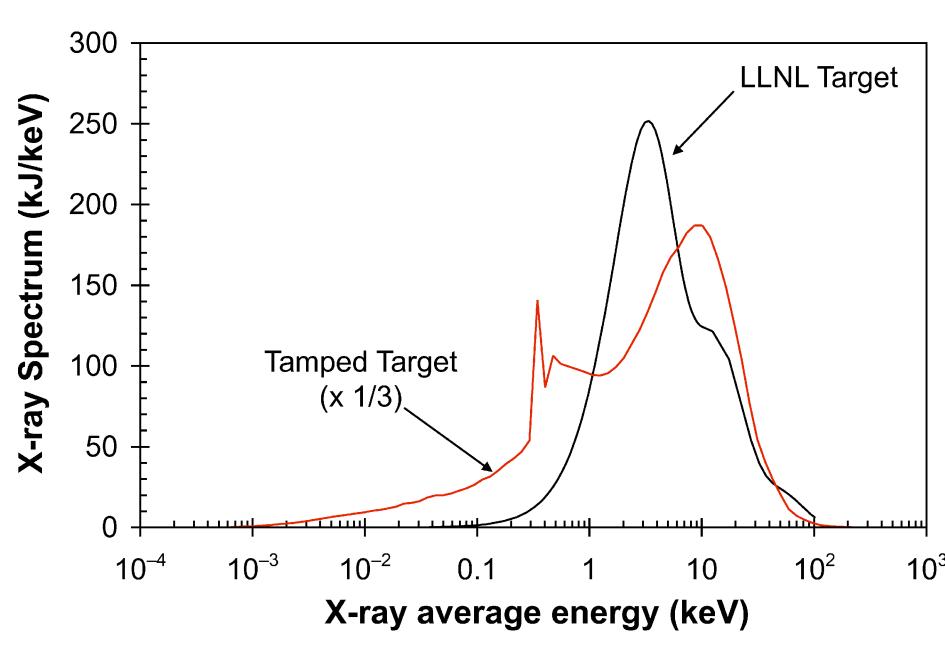

Plotted below are the x-ray and alpha spectra from both the HAPL target (produced by LLNL) and the BUCKY simulation of the tamped target design. Note that the energy from the high-energy alphas has been converted to x-rays by virtue of being stopped in the tamper region (0.5% of the fusion alphas escape the tamper).

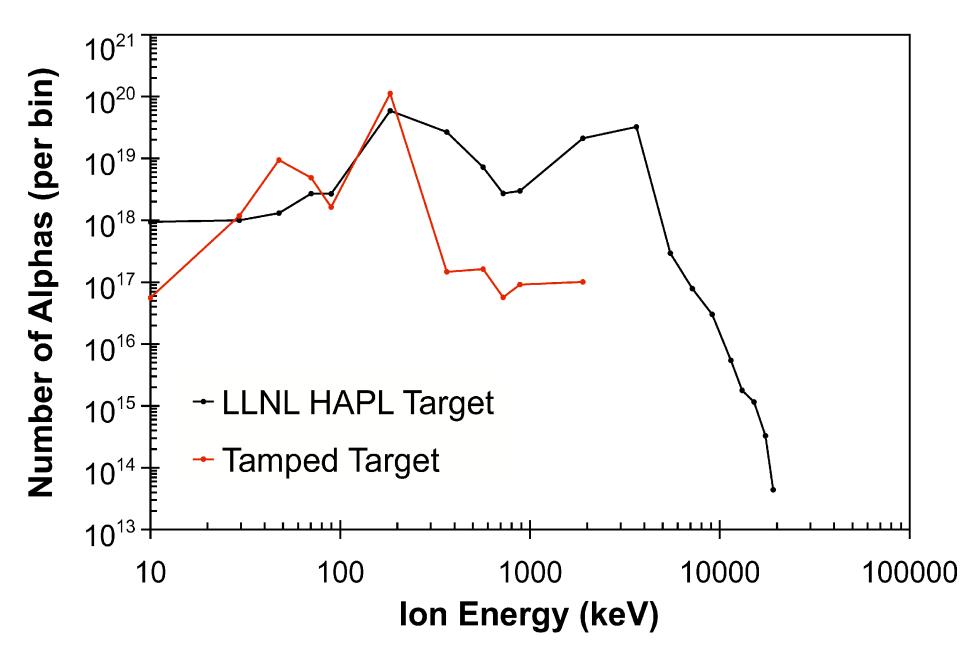

*This work supported in part by a grant from the Naval Research Laboratory, award no. N00173-03-1-G901.

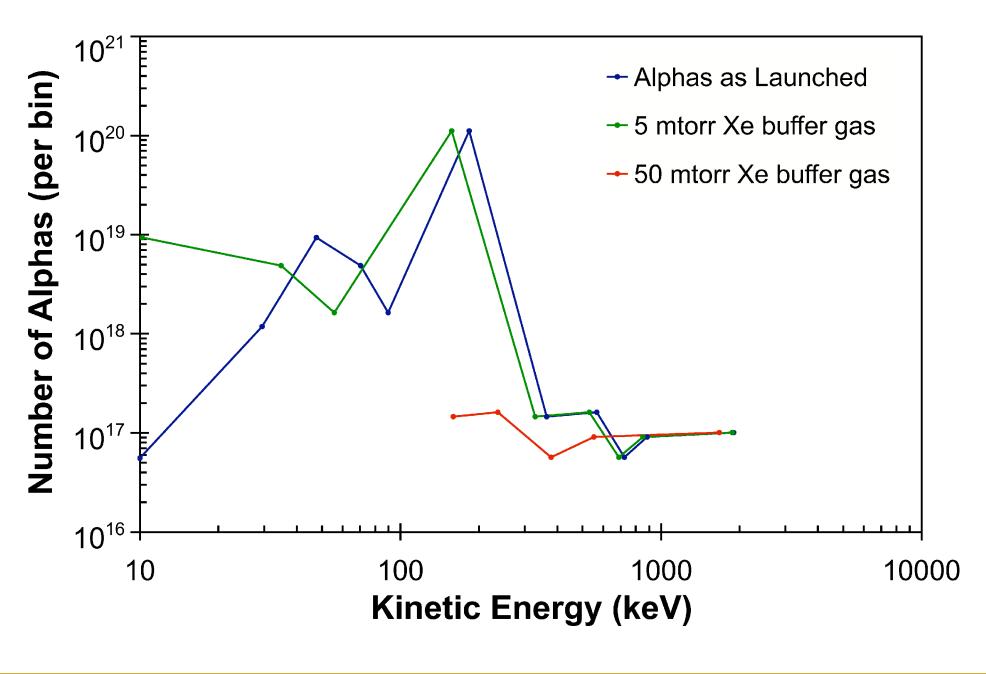

Comparison of x-ray and alpha spectra from the LLNL and Tamped Targets shows significant improvement in the threat spectra

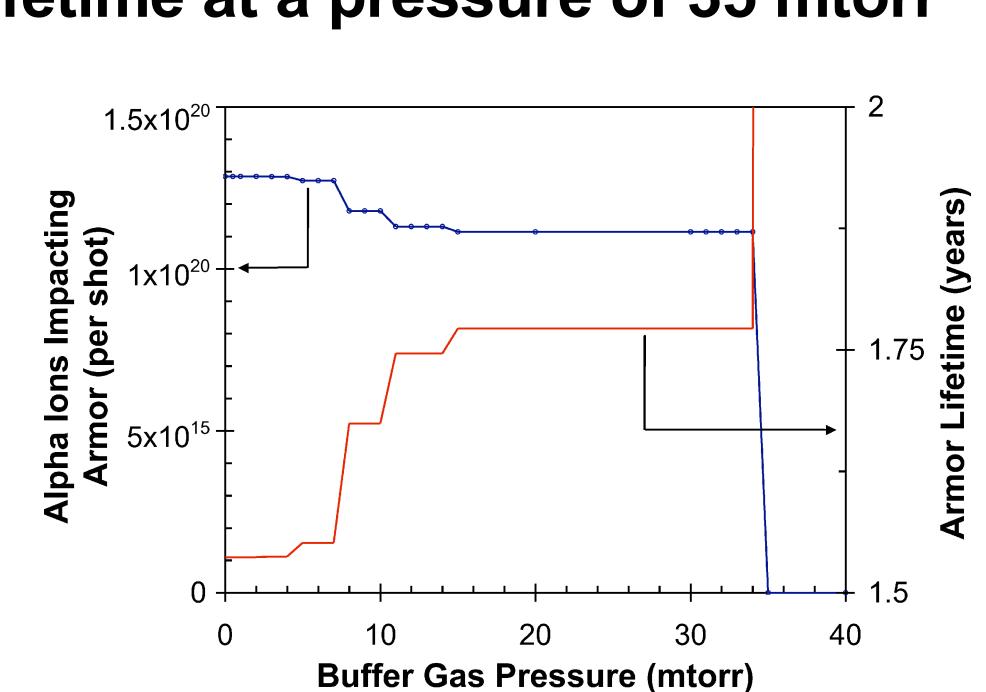

Chamber Buffer Gas is Essential

Xenon buffer gas stops the low-energy alphas, causing a significant increase in armor lifetime at a pressure of 35 mtorr

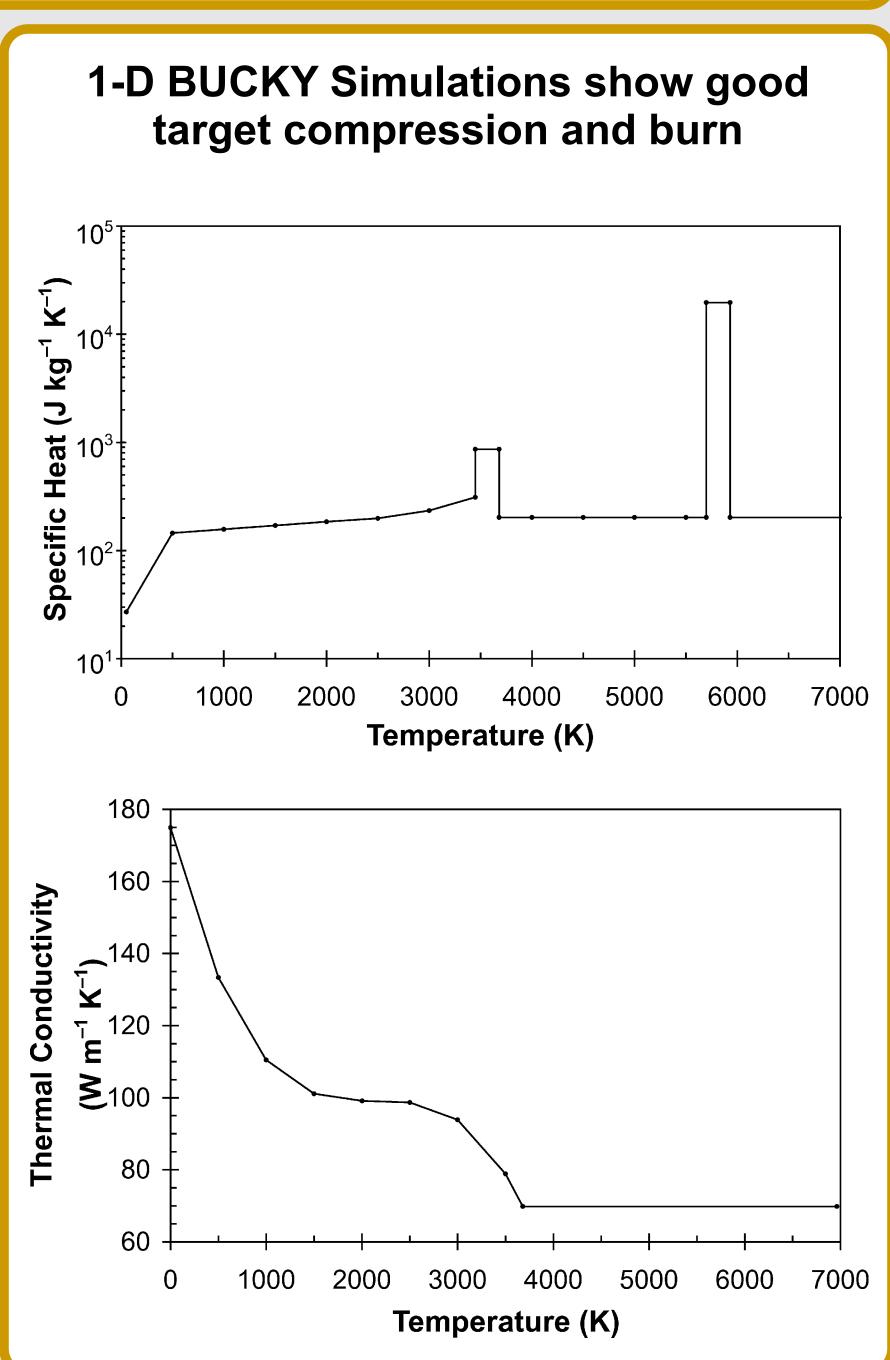

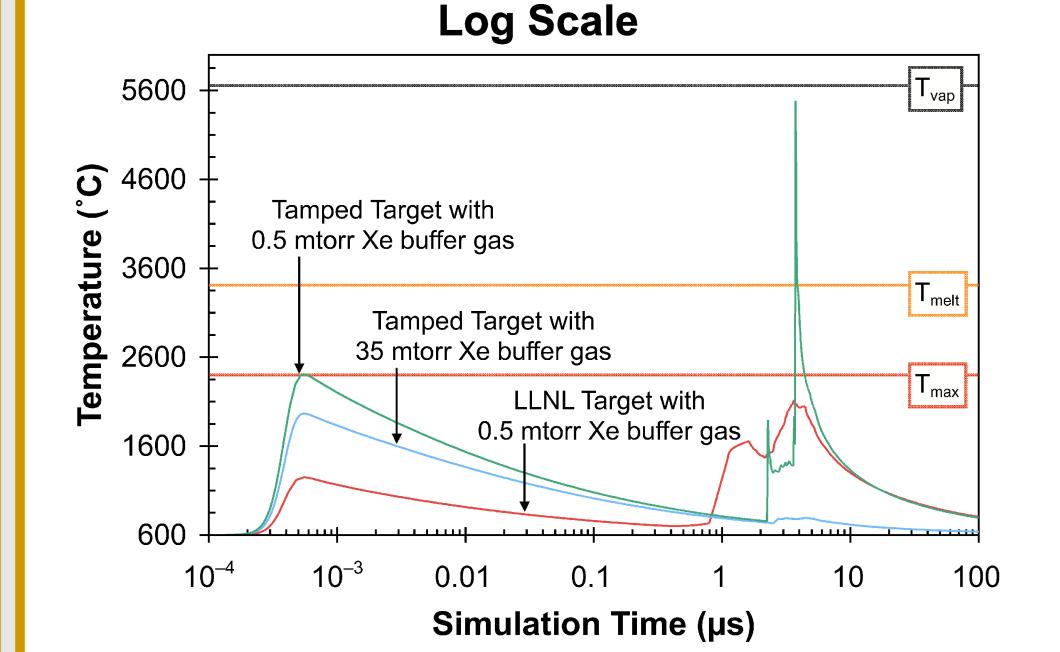

By itself, the tamped target design reduces the armor lifetime (from 2 FPY to 1½ FPY) by the production of more low-energy alpha particles. The tamped target design is only viable if used in conjunction with a low-pressure xenon buffer gas. Adding 35 mtorr of xenon buffer gas at 600 °C to the chamber is sufficient to stop nearly all alphas (see above), increasing the tungsten armor lifetime to 357 FPY (neglecting high-energy alpha and neutron damage).

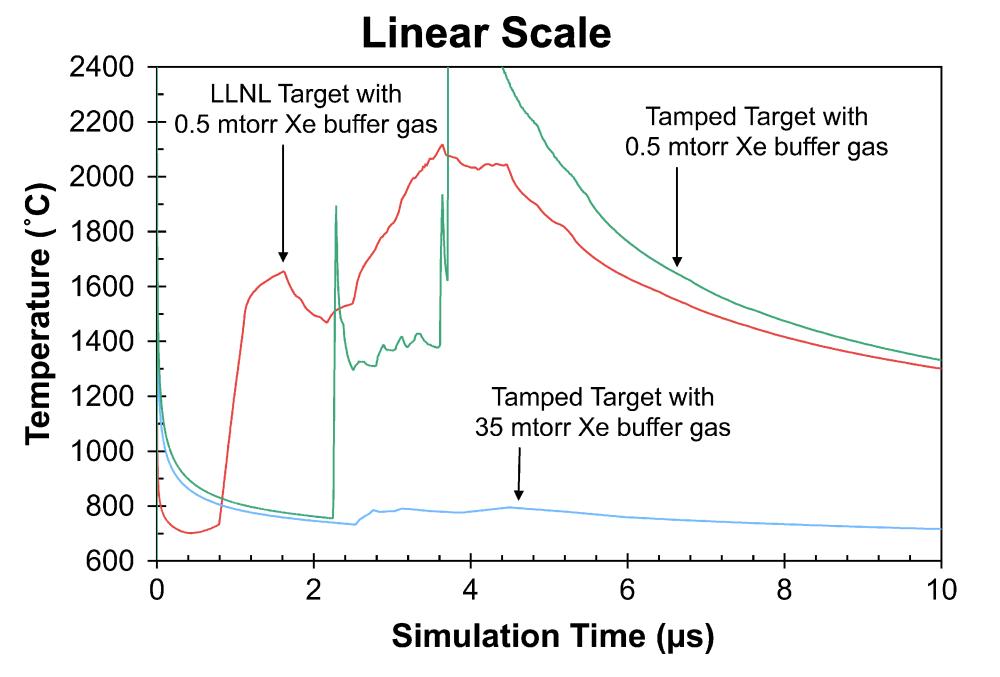

As shown below, the tamped target design in conjunction with 35 mtorr of xenon buffer gas also satisfies the thermal stress limiting criterion of a surface temperature maximum of no greater than 2400 °C.

Additional 2-D simulations need to be performed to ensure that the target has enough hydrodynamic stability to ignite and burn without drastic modifications to the laser power profile or total driver energy delivered to the target.

Using HED Experiments and Computer Codes in the Study of Target Chamber Dynamics and Astrophysical Phenomena

Robert R. Peterson

ABSTRACT

In this talk, I describe how HED (High Energy Density) experiments are used to study the physics of IFE target chamber dynamics, including the transition of radiation-driven blasts in low density media from supersonic to subsonic and the rapid melting and re-solidification by intense burst of x-rays and ions. I also discuss how these experiments are useful in validating computer codes that model such phenomena. I discuss the connection of these phenomena to astrophysical applications,

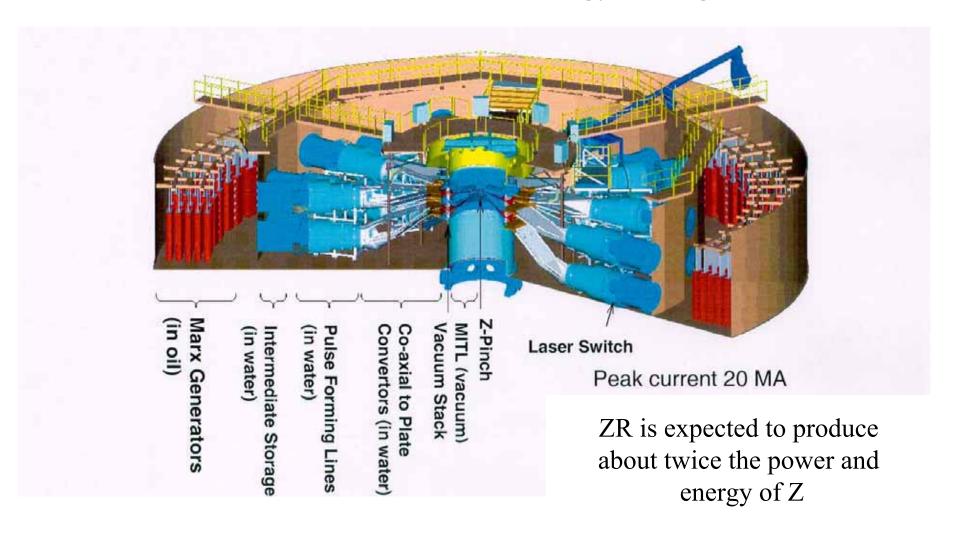

HED Experiments, Physical Models, and Computer Codes are Required to Study IFE and Astrophysics

Ionization fronts are observed in astrophysical systems

- Burst of UV photons from source (e.g. star, SN) ionizes medium - creates shock
- Shocked material emits photons
- Photons ionize medium ahead of shock.
- Ionization front is formed.
- Hot unshocked region is often referred as the precursor region.

Transonic Radiation Wave in SiO₂ Foam Creates a Radiation-Drive Shock, Which Can be Radiographed.

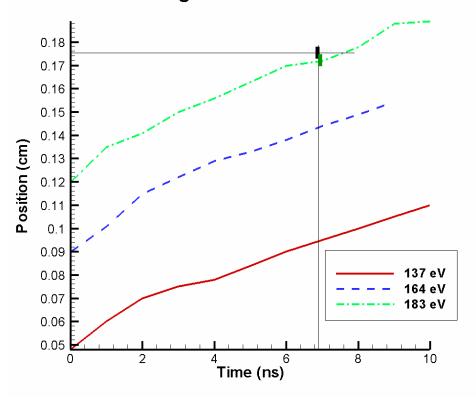

- •Radiation flows into the aerogel foam, initially as a supersonic, diffusive Marshak wave. The wave is moving faster than the foam can hydrodynamically respond to the pressure gradient applied at the radiation front.
- •As the volume behind the Marshak front increases, the radiation temperature drops and the Marshak wave slows.
- •Eventually, the Marshak wave slows to the speed of a shock in the foam. A radiation-driven shock is formed which is moving much slower than the initial Marshak wave and can be observed.

Observed Shock Position on Z1430 is Consistent with Radiation Power Observed Being Emitted from the Bottom of the DH

- Present codes and models are being applied to a number of astrophysical problems.

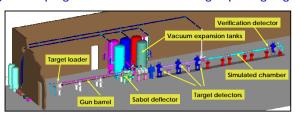

Target Injection and Engagement Ronald Petzoldt, Neil Alexander, Lane Carlson, Dan Goodin, Graham Flint, and Emanuil Valmianski

Significant progress was achieved with high-speed gas gun

We demonstrated:

- · Rep-rated operation (6 Hz. "burst" mode)
- Two-piece sabot separation and deflection
- · Membrane support of target in sabot
- Injection velocity of ≥400 m/s with time "jitter" at chamber center of ~ 0.5 ms (KrF requirement of < 1 ms)
- · Target placement accuracy standard deviation of 10 mm at 17 m

However, greater accuracy is needed.

Two piece sabot removal and gas removal add to system complexity and reduce accuracy

The magnetic intervention concept allows removal of chamber protection gas and smaller chamber size

Substantially changes target injection requirements

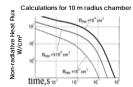

- Target survival (> ~25 m/s injection velocity)
- · Only one target in chamber at a time (> ~32 m/s at 5 Hz)
- · We are evaluating ~50-100 m/s
- 13-50 cm acceleration at 10,000 m/s2 Opens door for other injection mechanisms (Mechanical, pneumatic, electric, etc.)
- · Without gas in chamber, ±1 mm placement accuracy has been discussed - a challenge to be demonstrated
- · Without sabot separation and with in-chamber tracking, the target flight distance could be reduced from 17 m to ~10 m
- ...Magnetic intervention should make target injection easier (i.e. slower)

Calculations indicate that plasma heating is dramatically reduced with lower gas density

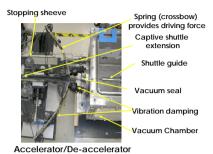

- Radiation only reduces gas temperature to ~10,000 K between shots Mean free path << chamber radius for n>10¹³/cm³ (0.3 mTorr)
- Plasma does not quickly recombine without contacting surfaces
- Plasma transfers recombination energy to targets

⇒Gas density <~1 mTorr may be necessary for acceptably low target

*Ref: Simulation of afterglow plasma evolution in an inertial fusion energy chamber, B.K. Frolov, A.Yu. Pigarov, S.I. Krasheninnikov R.W. Petzoldt, D.T. Goodin, Journal of Nuclear Materials 337-339 (2005) 206-210

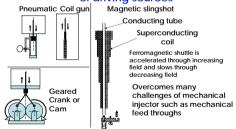

A single-shot mechanical injection device demonstrated improved injection accuracy

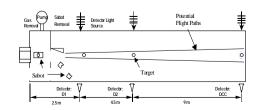

Injection method		Target Material	Mass		4 m, 1 σ accuracy	17 m, 1 σ Extrapolation
Gas gun best resu ~10-20 mTorr	ults	Solid Plastic	30 mg	L	NA	10 mm
Mechanical 10-20 mTorr with r static charge	educed	Hollow plastic	1 mg		0.9 mm	3.8 mm
Mass of an IFE target is about 8 mg						

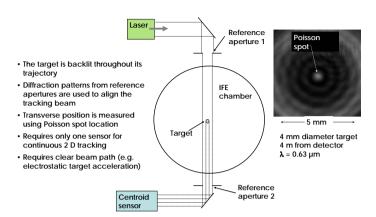

Low-speed injectors can be built using a number of driving sources

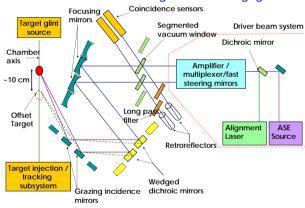

First step used two position measurements were previously used to predict final target position

Currently use continuous transverse position measurement for early mirror steering

The target itself provides a common reference point for final driver beam alignment and engagement

- · The alignment beam is longer wavelength than the driver so goes through the long pass filter and retroreflector to the coincidence sensor
- · A "glint" off the target enters the coincidence sensors.
- · Dichroic wedges compensate for target motion between the glint and driver beam arrival and also for the glint offset from target center.
- · Differences between the glint and alignment beam positions on the coincidence sensor are corrected with fast steering mirrors.

Summary

- · Higher accuracy demonstrated at reduced injection speed
- · Magnetic intervention allows very low gas density - May be required to avoid excessive target heating
- · Continuous target tracking is achieved by measuring Poisson spot motion from a backlit target
- Final beam-target alignment is facilitated by measuring position of a glint return off the target 1-2 ms prior to the shot.

IN FLIGHT TARGET STEERING TO IMPROVE INJECTION ACCURACY

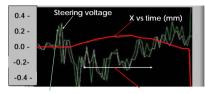

Introduction

Driver beams must be steered to hit targets with 20 µm accuracy with target speed ~100 m/s.

- Target steering can;
- Improve accuracy of target placement
- Reduce steering distance and speed required for ~3000 drive beamlets.
- Facilitate early FTF non-reprated operation with 50 cm standoff and no high-speed beam steering

We Integrated In-Flight Steering with **Real Time Trajectory Correction**

Control signal ∝V

Steering duration

Steering voltage based on X position (Poisson spot's centroid) and velocity updates each ~8 ms

$$V_i = -(2.4X_i + 60[X_i - X_{i-1}]) \,\mathrm{kV}$$

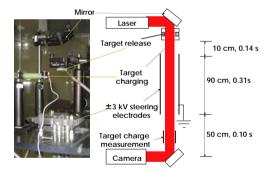

Target Steering is Accomplished with Multiple Real Time Electric Field Corrections

- · Electric charge is placed on the target
- · Target passes between long electrodes
- Target transverse position is measured each 8 ms
- · Electrode voltage is updated with each position

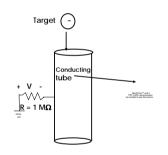

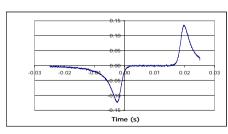

Charge on Falling Sphere is Measured Indirectly

$$q = \int I dt = \int \frac{V}{R} dt = -0.74 \text{ nC}$$

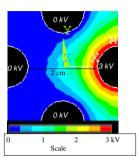

Standard deviation of charge is ~5 %

Two Axis Steering is Achieved with **4 Cylindrical Electrodes**

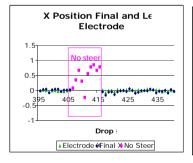

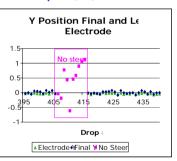

Electric field is less uniform with quadrupole steering electrodes than with parallel plates

We modified the steering algorithm to include this non-linearity

Placement Accuracy (2D) Improved from ~500 to ~50 µm (1_o)

Summary and Conclusions

- Improved target placement accuracy reduces required beam steering
- 10X accuracy improvement with electrostatic steering demonstrated
- Move from steering solid spheres in air to hollow spheres in vacuum
- Increase position measurement update rate (8 ms to ~1 ms)
- Move from dropped targets to higher-speed injection

Inaugural IFE Science & Technology Strategic Planning Workshop

San Ramon, CA

April 24-27, 2007

Outline

• Magnetic intervention as advanced option to reduce or eliminate ion threat on chamber wall

- Advanced chamber concept based on magnetic intervention
 - Self-cooled Pb-17Li or flibe with SiC_f/SiC

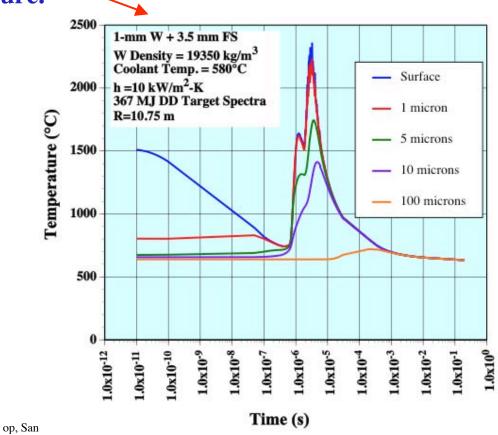

The HAPL Program Aims at Developing IFE Based on Lasers, Direct Drive Targets and Solid Wall Chambers

• Challenging to design dry wall armor to accommodate ion and photon threat spectra.

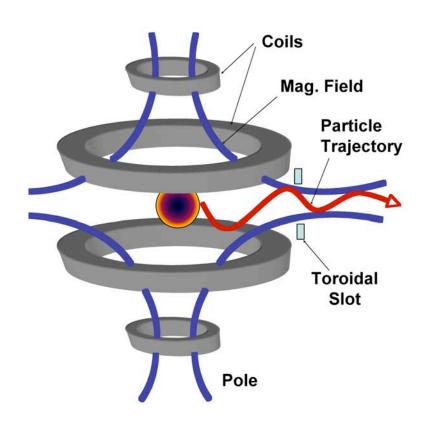

• For example, for baseline 350 MJ target (~24% of the energy is in ions and ~1% in photons), a large chamber (~10.75 m) is required to maintain W armor under a reasonable temperature.

- In addition, ion implantation (in particular He) can lead to exfoliation and premature failure of the armor.
- Maintain large chamber as baseline but look at advanced options that would reduce the ion threat spectra on the armor and allow for more compact chambers.
 - Magnetic intervention is such an option

Magnetic Intervention: Utilizing a Cusp Field to Create a Magnetic Bottle Preventing the Ions from Reaching the Wall and Guiding them to Specific Locations at the Equator and Ends

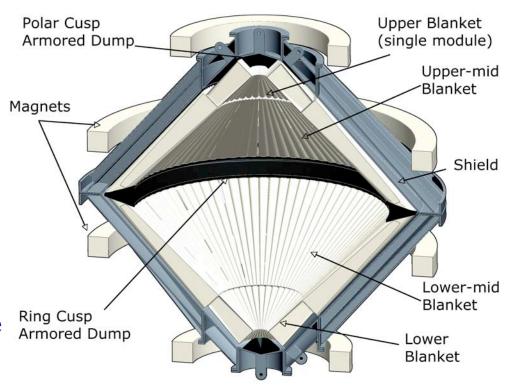

- Utilization of a cusp field for such magnetic diversion has been experimentally demonstrated previously.
 - 1980 paper by R.E. Pechacek et al.,
- Following the micro-explosion, the ions would compress the field against the chamber wall, the latter conserving the flux. Because of this flux conservation, the energetic ions would never get to the wall.
- One possibility would be to dissipate the magnetic energy resistively in the FW/blanket, which reduces the energy available to recompress the plasma and reduces the load on the external dumps.
 - about 70% of ion energy dissipated in blanket
 - about $30\,\%$ of ion energy in dump region

Conical Chamber Well Suited to Cusp Coil Geometry and Utilizing SiC_f/SiC for Resistive Dissipation

- Armored ion dumps could be inside the blanket chamber (as schematically shown) or outside, which is the preferred configuration allowing for easier maintenance.
- SiC_f/SiC blanket with liquid breeder.
- Water-cooled steel shield (~0.5 m thick) required to protect the coil (behind the blanket or around coil).
- Design provides for accommodation of laser ports.

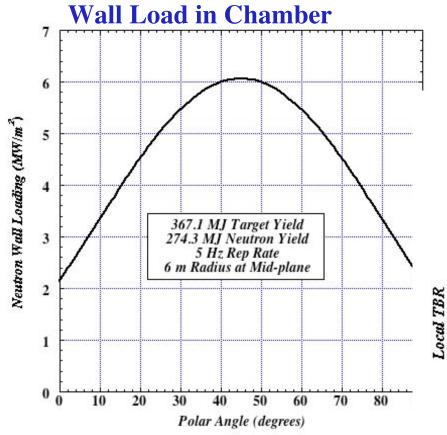

• Preferred design includes an external vacuum vessel with maintenance performed from the top.

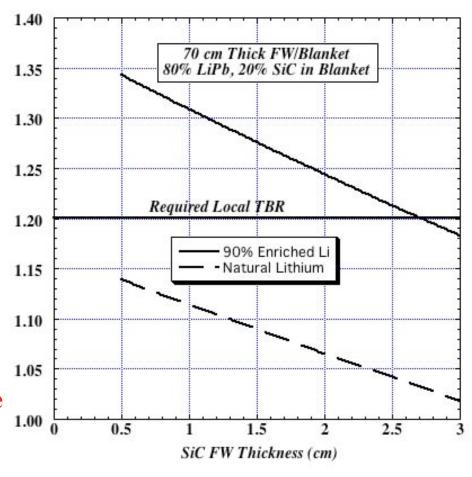

Neutronics Analysis Indicates Acceptable Tritium Breeding and Blanket Module Lifetime

Angular Distribution of Neutron

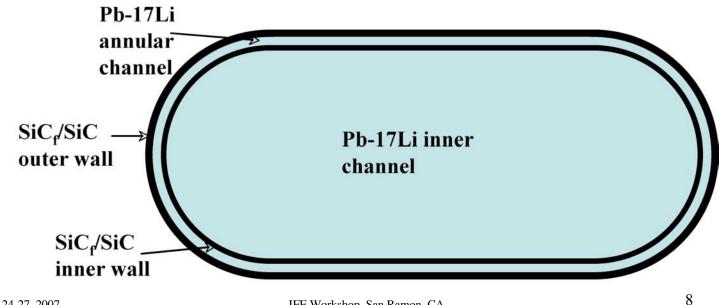

• Assuming a 3% burnup limit for SiC 1.05 (corresponding to 260 dpa, 16,300 He appm, and 6,370 H appm), the blanket lifetime is 3.26 FPY

Flexibility in setting TBR by adjusting ⁶Li enrichment for different SiC_f/SiC FW thickness for Pb-17Li case

Self-Cooled Pb-17Li +SiC_f/SiC Blanket Optimized for **High Cycle Efficiency**

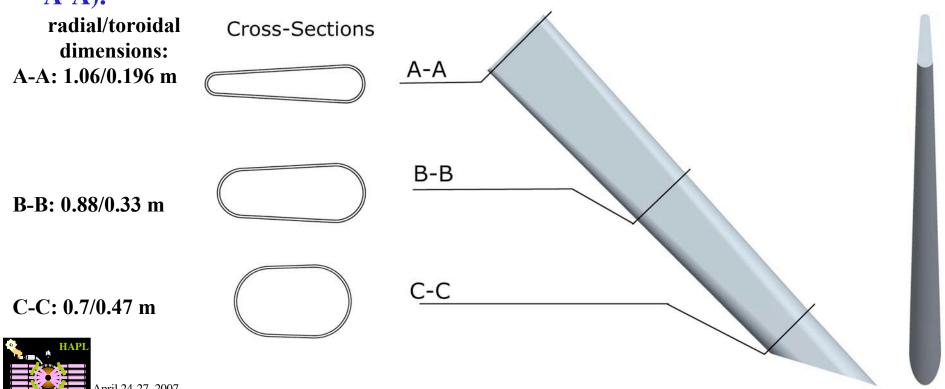

- Simple annular submodule design builds on ARIES-AT concept.
- Pb-17Li flows in two-pass: first pass through the annular channel to cool the structure; and a slow second pass through the large inner channel where the Pb-17Li is self-heated.
- This allows for decoupling of the outlet Pb-17Li temperature from the maximum SiC_f/SiC temperature limit.

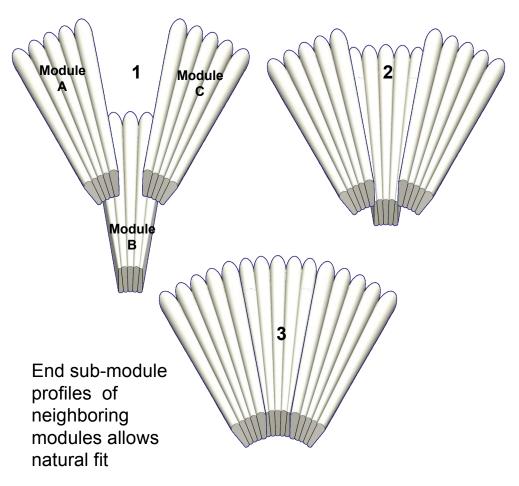

Submodule Configuration for Upper Mid-Blanket Region

- Submodule cross-section changes because of conical geometry.
- Pb-17Li enters through annular channel at equator (C-C), turns at top (A-A), flows through inner channel and exits at A-A.
- 5 submodules joined (e.g. by brazing) to form a modular unit for assembly and maintenance.
- Tight fit assembly so that all submodules are pressure-balanced by adjacent modules to avoid large stresses associated with long radial span (particularly at A-A).

Submodules Shaped at Module End for Tight Fit Assembly and Pressure-Balancing of All Submodules

- Concerns exist about the possible domino effect on all submodules in case of a catastrophic failure of a submodule.
- Possible solutions include isolating a limited number of modules by including structurally independent wedges and/or using pressure-sensitive valve system to drain and decompress the coolant in such an accident case.

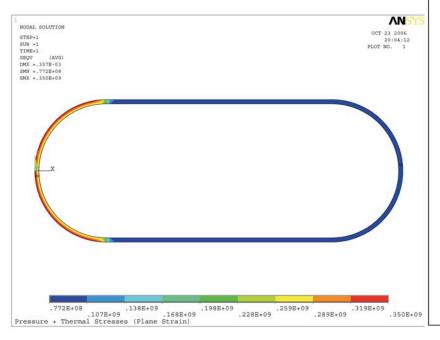

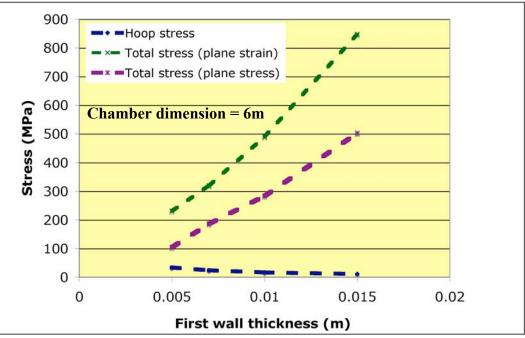

2-D Stress Analysis of First Wall Performed with ANSYS

- At B-B, maximum heat loads: $q''=0.11 \text{ MW/m}^2$; $q_{SiC}'''=31 \text{ MW/m}^3$.
- Pb-17Li pressure = 1 MPa (accounting for hydrostatic pressure \sim 0.33 MPa for \sim 4 m elevation, $\Delta P_{blkt} \sim$ 0.2 MPa and some margin).
- σ_{tot} increases sharply as the wall thickness is increased, indicating the dominating effect of the increasing $\sigma_{thermal}$ over the decreasing $\sigma_{pressure}$.
- For the present scoping design analysis, it seems reasonable to choose δ_{FW} ~5 mm; the corresponding σ_{tot} ~100 MPa for plane stress and ~230 MPa for plane strain , compared to an assumed limit of ~190 MPa for SiC_f/SiC.

• If more margin is needed in the future, a slightly thinner wall of larger chamber could be used.

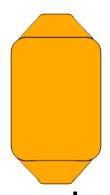

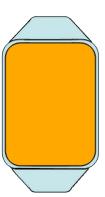

Possible Submodule Fabrication Method (rectangular submodules shown for illustration)

Issue: Complex concentric walls prevent assembly of inner and outer channels

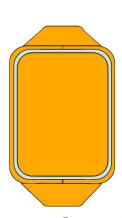

Solution: Expendable core form fabrication

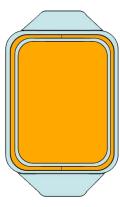

1. inner channel form

2. Lay-up & infiltrate inner channel

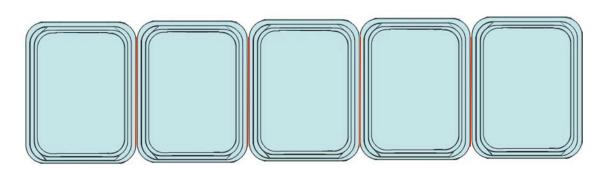

3. Two-piece form fitted over inner channel

4. Lay-up & infiltrate outer channel

6. Braze end caps

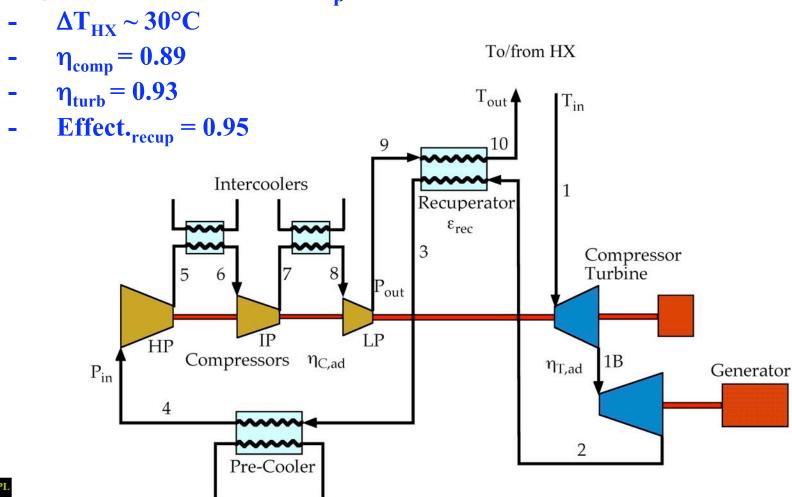

5. Consume both forms via chemical or thermal process

7. Braze 5 submodules together to form module

UCSanDiego

Self-Cooled Pb-17Li + SiC_f/SiC Blanket Coupled to a Brayton Cycle though a Pb-17Li/He HX

• 3 Compressor stages (with 2 intercoolers) + 1 turbine stage; $\Delta P/P \sim 0.05$; 1.5 < $r_p < 3.5$

UCSanDiego

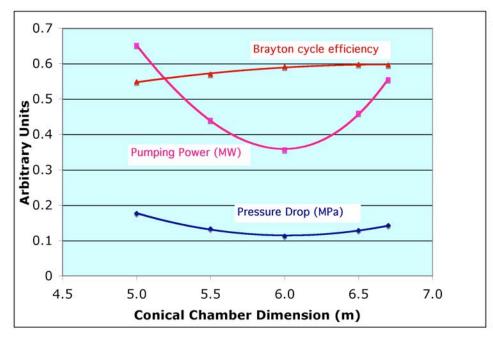

Thermal-Hydraulic Optimization Procedure

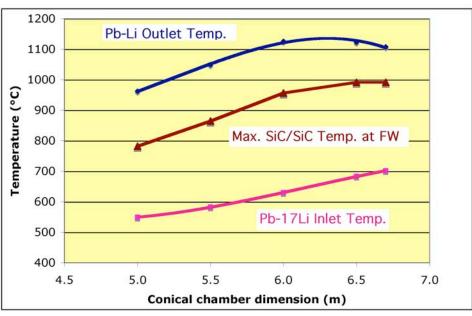

- Set blanket design parameters.
 - SiC_f/SiC δ_{FW} =0.5 cm; $\delta_{annulus}$ =0.5 cm
 - only the blanket length is adjusted based on the chamber size
- Simple MHD assumption based on assumed 1 T field and flow laminarization with conduction only (probably conservative).
- For given chamber size and fusion power, calculate combination of inlet and outlet Pb-17Li temperatures that would maximize the cycle efficiency for given SiC_f/SiC temperature limit and/or Pb-17Li/SiC interface temperature limit.
 - $SiC_f/SiC T_{max} < 1000$ °C
 - Pb-17Li/SiC T_{max} <950°C
 - Assume conservatively k=15 W/m-K for SiC_f/SiC

Target yield	367 MJ		
Neutron/ion/photon energy	0.75/0.24/0.01		
partition			
Rep rate	5		
Fusion power	1837 MW		
Energy multiplication factor	1.19		
Total thermal power	2080 MW		
Cone height/radius	6/6 m		
Peak/avg. neutron wall load	$6.1/4.3 \text{ MW/m}^2$		
Peak power density in SiC	31 MW/m^3		
Peak/avg. photon heat flux on	0.11/0.08		
first wall	MW/m^2		

Brayton Cycle Efficiency as a Function of Cone-Shaped Chamber Size and Corresponding Outlet and Inlet Pb-17Li Temperatures

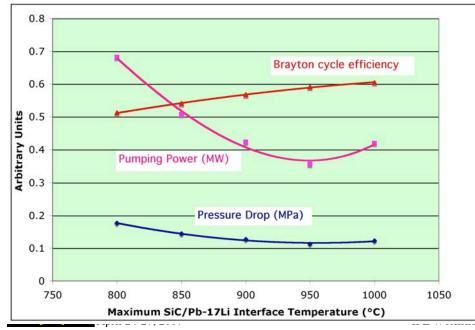

- Pb-17Li/SiC T_{max} < 950°C is more constraining than SiC_f/SiC T_{max} <1000°C
- Both ΔP and P_{pump} show minima at a chamber dimension of 6 m corresponding to the largest ΔT between Pb-Li inlet and outlet temperatures (and lowest flow rate).
- For a 6 m chamber, Pb-17Li T_{out} ~1125°C; $\eta_{Brayton}$ ~0.59
- Question about whether such a high Pb-17Li T_{out} can be handled in out of reactor annular piping and in heat exchanger.

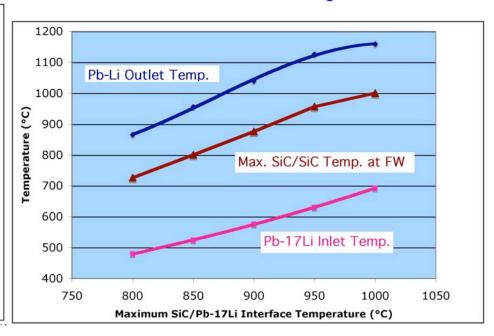

Effect of Varying the Pb-17Li/SiC Interface Temperature Limit

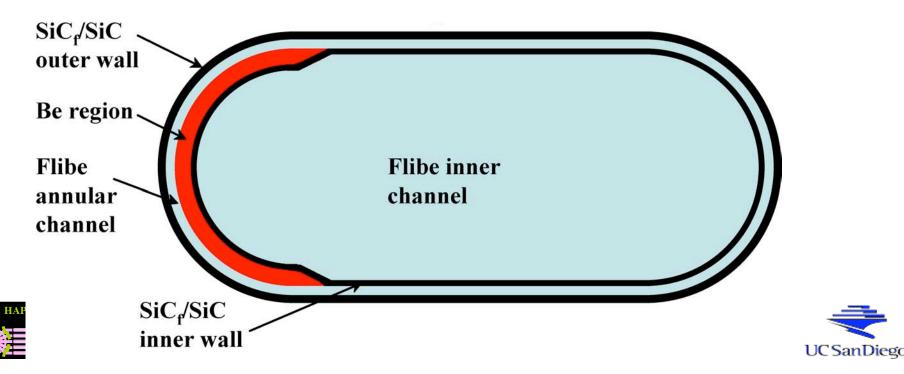

- It is not clear what the allowable SiC/Pb-17Li T_{max} really is as it depends on a number of conditions.
- Earlier experimental results at ISPRA indicated no compatibility problems at 800°C, whereas more recent results indicate a higher limit.
- Decreasing the SiC/Pb-17Li T_{max} from 950°C to 800°C results in a marked reduction in cycle efficiency, from ~59% to ~50%.
- Interestingly, the pressure drop and pumping power minima correspond to an interface limit of 950°C, and both increase significantly as the interface temperature limit is decreased and an increased in flow rate is required.

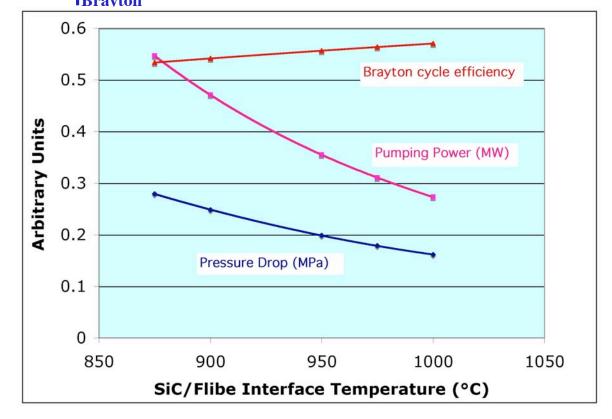

Adapting the Blanket for Flibe Requires a Be region for Tritium Breeding

- 1-1.5 cm Be region sufficient for TBR~1.1
- A Be plate can be included in the previous submodule design.
- Be also used for chemistry control of flibe.
- The flibe flows in two-pass: a first pass through the annular channel to cool the structure; and a slow second pass through the large inner channel where the flibe is self-heated.

Effect of Varying the Flibe/SiC Interface Temperature Limit

- Flibe T_{out} < Pb-17Li T_{out} mostly because of its poorer heat transfer properties.
- For 6 m conical chamber and 1000°C limit: flibe Tin/Tout = 673/1000°C; Be T_{max} = 840 °C ΔP = 0.16 MPa; P_{pump} = 0.27 MW $\eta_{Bravton}$ = 0.57

6 m chamber SiC_f/SiC T_{max} < 1000°C:

Summary

- A scoping design analysis has been performed of a self-cooled liquid breeder (Pb-17Li or flibe) + SiC_f/SiC blanket concept for use in the magnetic-intervention cone-shaped chamber geometry.
 - Simple geometry with ease of draining and accommodation of 40 rectangular laser ports with vertical aspect ratio .
 - Good performance, with the possibility of a cycle efficiency >50% depending on chamber size and SiC_f/SiC properties and temperature limits.
 - Submodule side walls are pressure-balanced; only the first wall and back wall are designed to accommodate the loads.
 - Must be noted that SiC_f/SiC is an advanced material requiring substantially more R&D than more conventional structural material (e.g. FS).
 - Submodule design can be adapted to flibe as breeder by adding a layer of Be to ensure a TBR of 1.1 and provide for chemistry control.
 - The high coolant temperatures result in high cycle efficiency and could also be used for H₂ production.
 - However, issues of what outside coolant tube and HX material(s) to use at these temperatures need to be further investigated.

Pressurized gas as a driver for Magnetized Target Fusion*

D.D. Ryutov Lawrence Livermore National Laboratory, Livermore, CA 94551 Y.C. F. Thio US Department of Energy, Germantown, MD 20874, USA

(Presented at the ICC-07 Workshop, College Park, MD, Skunkworks session, February 14, 2007)

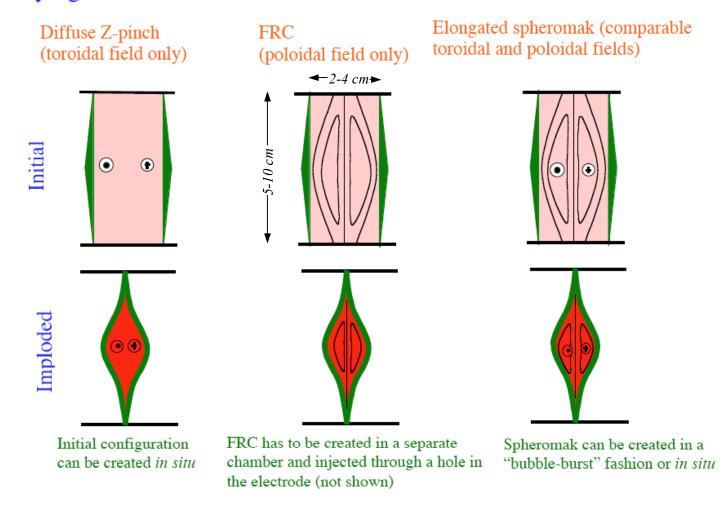

^{*} Work performed for the U.S. DoE by UC LLNL under contract # W-7405-Eng-48.

THE SCOPE

- Magnetized Target Fusion (MTF) is a term designating a broad variety of approaches based on a unifying idea of adiabatic compression of a pre-formed magnetized β >1 plasma by a conducting liner
- MTF systems span a broad range of plasma parameters intermediate between magnetic confinement and inertial confinement
- We concentrate on a version of MTF that involves 3D implosions of a wall-confined plasma with the density in a compressed state $\sim 10^{22}$ cm⁻³, with energy in $\sim 10\text{--}30$ MJ and energy out ~ 300 MJ; the current \sim a few MA, current pulselength $\sim 5\text{--}10$ μs .

This fusion concept has a long history; a summary of the earlier work can be found in R.P. Drake, J.H. Hammer, C.W. Hartman, L.J. Perkins, D.D. Ryutov. "Submegajoule liner implosion of a closed field line configuration," Fusion Technology, 30, 310, 1996.

A variety of targets can be imploded in a 3D fashion by a liner of a varying thickness

We concentrate on a possible solution of the stand-off problem

An earlier work in this area:

Mechanical insertion of the target and disposable transmission line to a large chamber. (R.W. Moses, R.A. Krakowski, R.L. Miller. "A conceptual design of the Fast-liner Reactor (FLR) for Fusion Power." LANL report LA-7686-MS, February 1979)

Driving a magneto-cumulative generator by a fast projectile. (R.P. Drake, J.H. Hammer, C.W. Hartman, L.J. Perkins, D.D. Ryutov. "Submegajoule liner implosion of a closed field line configuration," Fusion Technology, **30**, 310, 1996)

Delivering the current by a particle beam (inverse diode technique). (R.P. Drake, J.H. Hammer, C.W. Hartman, L.J. Perkins, D.D. Ryutov. "Submegajoule liner implosion of a closed field line configuration," Fusion Technology, **30**, 310, 1996)

Using a set of converging, high Mach-number plasma jets. (Y.C.F. Thio, C.E. Knapp, R.C. Kirkpatrick, R.E. Siemon, P.J. Turchi. "A physics exploratory experiment on plasma liner formation," J. Fusion Energy, 20, 1, 2001; P.B. Parks, Y.C.F. Thio. "The dynamics of Plasma Liners Formed by Merging of Supersonic Plasma Jets," Prepared for submittal to Phys. Plasmas)

Using a spherical liner made of high-Z plasma driven by subsonic thermal plasma. (D.D. Ryutov, Y.C.F. Thio. "Plasma liner with an intermediate heavy shell and thermal pressure drive", Fusion Sci. Technol., **49**, 39-55, 2006).

Using plasma streams as disposable electrodes. (D.D. Ryutov, Y.C.F. Thio. "Solving the stand-off problem for Magnetized Target Fusion: plasma streams as disposable electrodes, together with a local spherical blanket." Journal of Fusion Energy, http://dx.doi.org/10.1007/s10894-006-9050-5, 2006).

We consider the use of a pressurized gas as an energy source for MTF

This work is an extension of our previous studies of plasma liners

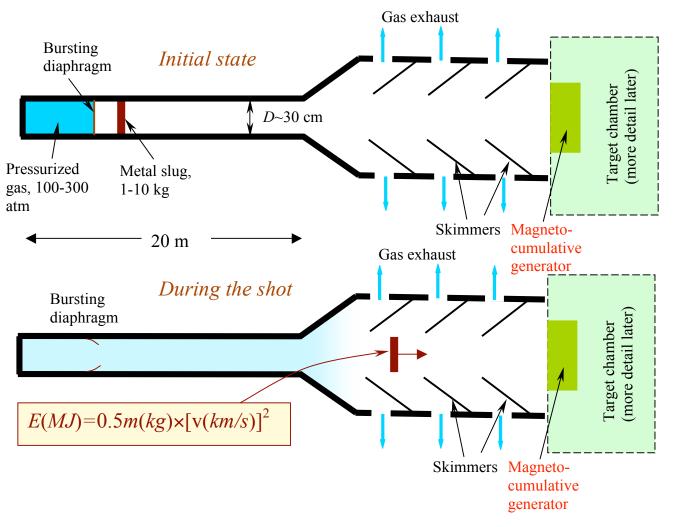

Pressurized gas has been considered earlier as a driver for liquid lithium liner in the LINUS concept (P.J. Turchi. "A Compact-Toroid Fusion Reactor Design at 0.5 Megagauss, Based on Stabilized Liner Implosion Techniques," 3rd Int. Conf. on Megagauss Magn. Field, Novosibirsk, 1984, p.p.184-201)

This was a slow drive, ~ 1 ms time-scale

We consider a possibility of using the pressurized gas to drive the current pulse of $\sim 10~\mu s$ duration suitable for the centimeter-size liner implosion in MTF

This is not an end-to-end analysis of a particular version of a fusion reactor, just some thoughts of pros and cons of a possible solution of the stand-off problem

The pressurized gas will be used to accelerate a heavy metal slug in a gas-gun configuration

will compress the bias magnetic field in the magneto-cumulative generator (MCG) and generate a 10-15 μs current pulse, suitable for driving the imploding liner.

A more detailed picture of a slug (expanded)

Using nitrogen (or even air) as a driving gas has a number of advantages:

Inexpensive

Relatively harmless

Can be exhausted back to the atmosphere (after possible chemical cleaning and tests for the absence of radioactive substances)

Parameters of nitrogen

- Molecular weight *M*=28;
- Adiabatic index $\gamma=7/5$;
- Sound speed

$$s(m/s) = 350\sqrt{\frac{T({}^{o}K)}{273}}$$

Maximum expansion speed (very light slug)

$$v_{\text{max}} = \frac{2s}{\gamma - 1} = 5s$$

- Mass density $\rho(kg/m^3)=1.25\times p(atm)\times[273/T(^oK)]$
- Stored energy density $W(MJ/m^3) \approx 0.1 \times p(atm)$ $W(MJ/kg) = 0.082 \times [T(^{\circ}K)/273]$

The performance would be significantly better for (a much more expensive) helium: higher slug velocities, higher efficiencies at the same pressure

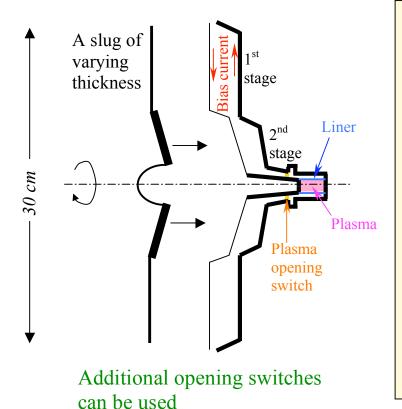

Parameters of the acceleration system

- Acceleration efficiency η is determined by that the nitrogen gas has finite energy at the end of the pulse; it can be as low as ~ 0.5 for a properly chosen mass of the slug
- The achievable slug velocity: $v=0.5v_{max}=2.5s=0.875[T(K)/273]^{1/2}$ km/s (for a reasonable efficiency)
- Evaluate the gas volume: $V(m^3) \sim 10E(MJ)/\eta p(atm)$ [V ~ 0.7 m³ for E=10 MJ, p=300 atm, $\eta=0.5$]
- •The gun length ~ 10 m for the diameter ~ 30 cm.
- The achievable slug energy $(E=mv^2/2)$:

$$E(MJ) = 0.38m(kg) \times [T(^{\circ}K)/273]^{1/2} \sim 0.7 \text{ m (kg) [a gas heated to } \sim 500 ^{\circ}C].$$

- •The slug parameters: r=15 cm, density $\rho=10$ g/cm³, thickness h=2 cm (mass m=14 kg)
- Characteristic time of the energy delivery to MCG: $\sim h/v=15 \mu s$

A multistage magneto-cumulative generator would allow converting the slug energy into the energy of the current pulse*

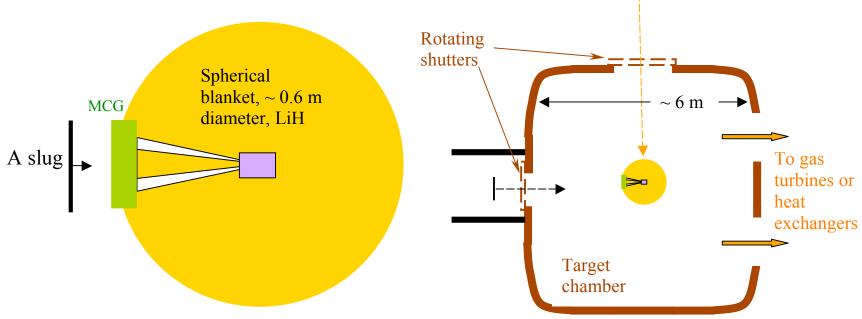

Some parameters of MCG:

- Initial volume of the 1st stage 10 *l*
- Initial magnetic field 30 kG
- Initial volume of the second stage 3 *l*
- The magnetic field before the beginning of compression of the 2nd stage 150 kG
- The volume occupied by the magnetic field prior to the opening of POS 0.5 *l*
- The magnetic field 2 MG
- The pulse-width on the load 5 μs

^{*} The MCGs have been a subject of detailed experimental and computational studies in 1980s-1990s; a lot of relevant information can be found in: J.H. Degnan, et al. Proc. 3rd Int. Conf. on Megagauss Magn. Field, Novosibirsk, 1984, p.p.352-358; C.M. Fowler, et al., ibid. p.p.282-291.

The magneto-cumulative generator can be built-in to the assembly that carries the MTF target and local spherical blanket.

A local blanket (yellow) partly evaporated in every pulse. Breeds tritium and may beused as a working fluid (e.g., B.G. Logan. Fusion Engineering and Design, v. 22, p. 1953, 1993).

A possible general layout of a reaction chamber and a fast slug delivering energy to MCG (integrated with the spherical blanket)

SUMMARY

The pressurized nitrogen (helium) may become a simple and inexpensive energy source for MTF

Stored energy in the range of tens of megajoules is feasible for reasonable initial volumes

The metal slug with a mass of 10-30 kg can be accelerated to velocities $\sim 1.5-2$ km/s (2.5 – 3 km/s for helium) in a 20-m-long barrel

A hydrodynamic efficiency ~ 50% is feasible

Rep rate of a few Hz seems to be possible

Collision of a slug with a magneto-cumulative generator (MCG) can be used for converting its energy into the energy of a current pulse suitable for driving the MTF target

MCG can be integrated into the overall assembly that would be dropped into reaction chamber at a rate of a few Hz

<u>Issues for the further analysis</u>

Stable acceleration of a slug; possible use of a hydrodynamic stabilization

Preventing the evaporated blanket from bursting into acceleration/gas exhaust volume (rotating, non-vacuum-tight shutter followed by differential pumping system?)

The degree of contamination of the used driver gas

What happens to the slug? Can it melt (and evaporate) under the action of the neutron heating?

What techniques can be used for generating seed magnetic field in the MCG? Particle beams? Long-wavelength lasers? Disposable plasma electrodes?

Can the cost of every shot be made less than \$ 3 ?! (mass production?)

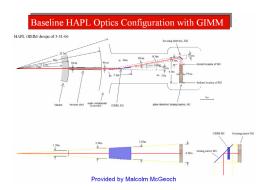

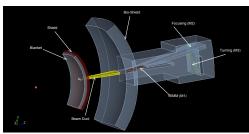

Three-Dimensional Nuclear Analysis for the Final Optics System of HAPL

Mohamed Sawan, Ahmad Ibrahim, Tim Bohm, Paul Wilson

Fusion Technology Institute - University of Wisconsin, Madison, WI

Objectives

Determine nuclear environment at the GIMM (M1), focusing mirror (M2), and turning mirror (M3) final optics of HAPL

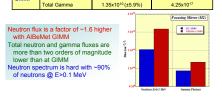

Assess impact of GIMM design

Flux at Front Faceplate of GIMM

		Flux (cm ⁻² .s ⁻¹)
SIC GIMM	Neutrons E>0.1 MeV Total Neutrons Total Gamma	1.39x10 ¹³ (±2.1%) 1.43x10 ¹³ (±2.1%) 1.57x10 ¹² (± 5.5%)
AlBeMet GIMM	Neutrons E>0.1 MeV Total Neutrons Total Gamma	1.21x10 ¹³ (±2.1%) 1.30x10 ¹³ (±2.1%) 1.88x10 ¹² (±4.4%)

Material choice and thickness slightly impacts peak flux in GIMM Neutron spectrum softer for AlBeMet with 93% >0.1 MeV compared to 97% for SiC

Flux at Focusing Dielectric Mirror M2 Located @14.9 m from GIMM (cm⁻² s⁻¹ 2.05x10¹⁰ (±4.0%) 6.46v101 Total Neutrons 2.27x1010(±4.0%) 7.15x1013 Neutrons E>0.1 Me 3.18x10¹⁰ (±3.9%) 3.57×1010 (±3.8%)

Peak Fast (E>0.1 MeV) Neutron Fluence per Full Power Year at Mirrors in Final Optics of HAPL

	Peak Fast Neutron Fluence per FPY (n/cm²)		
	SiC GIMM	AlBeMet GIMM	
GIMM (M1)	4.38x10 ²⁰ (±2.1%)	3.81x10 ²⁰ (±2.1%)	
Focusing Mirror (M2)	6.46x10 ¹⁷ (±4.0%)	1.00x10 ¹⁸ (±3.9%)	
Turning Mirror (M3)	1.00x10 ¹⁶ (±7.3%)	1.62x10 ¹⁶ (±7.6%)	

the HAPL program at the Naval Research Laboratory.

Approach

- > Used Monte Carlo code MCNPX-CGM with direct neutronics calculations in CAD model
- ➤ Continuous energy FENDL-2.1 nuclear data
- > Modeled one beam with reflecting boundaries ➤ Neutron traps used behind GIMM and M2
- > Two lightweight GIMM design options considered (SiC, AlBeMet)
- ▶ 1 cm thick Sapphire M2 and M3 mirrors
- > Blanket/shield included in model
- Concrete containment building housing optics

Geometrical Model Used in 3-D Neutronics Analysis

> 3-D neutronics calculation performed to determine nuclear environment in the HAPL final optics and compare impact of possible GIMM design options

Findings and Conclusions

Fast Neutron Flux Distribution in Final Optics of HAPL

- Neutron flux at dielectric mirrors is higher by a factor of ~1.6 with AlBeMet
- ➤ Neutron spectrum softens significantly at M3 (~40% >0.1 MeV vs. ~90% at M2)
- > Peak fast (E>0.1 MeV) neutron fluence per FPY: 4.4x10²⁰ n/cm² **GIMM**

1.0x1018 n/cm2 M2 1.6x1016 n/cm2

SiC GIMM

- Significant drop in nuclear environment occurs as one moves from the GIMM to dielectric focusing and turning mirrors
- Experimental data on radiation damage to metallic and dielectric mirrors are essential for accurate lifetime prediction
- For fluence limits of 10²¹ n/cm² (GIMM) and 10¹⁹ n/cm² (dielectric), expected GIMM lifetime is ~2 FPY, expected M2 lifetime is 10 FPY, and M3 is lifetime component

		Peak Flux (cm ⁻² .s ⁻¹)	Peak Fluence per full power year (cm ⁻²)
SIC GIMM	Neutrons E>0.1 MeV Total Neutrons Total Gamma	3.18x10 ⁸ (±7.3%) 8.44x10 ⁸ (±8.2%) 7.51x10 ⁸ (±8.0%)	1.00x10 ¹⁶ 2.66x10 ¹⁶ 2.37x10 ¹⁶
AIBeMet GIMM	Neutrons E>0.1 MeV Total Neutrons Total Gamma	5.14x10 ⁸ (±7.6%) 1.31x10 ⁹ (±8.8%) 1.01x10 ⁹ (±5.5%)	1.62x10 ¹⁶ 4.13x10 ¹⁶ 3.18x10 ¹⁶

Neutron flux is a factor of ~1.6 higher with AIReMet GIMM Total neutron flux is about two orders of magnitude lower than at M2 with smaller gamma flux reduction Neutron spectrum is softer with ~40% of neutrons @ E>0.1 MeV

Modeling Ion Stopping for Warm Dense Matter Experiments

Peter Stoltz, Seth Veitzer Tech-X Corporation, Boulder, CO

> John Barnard LLNL

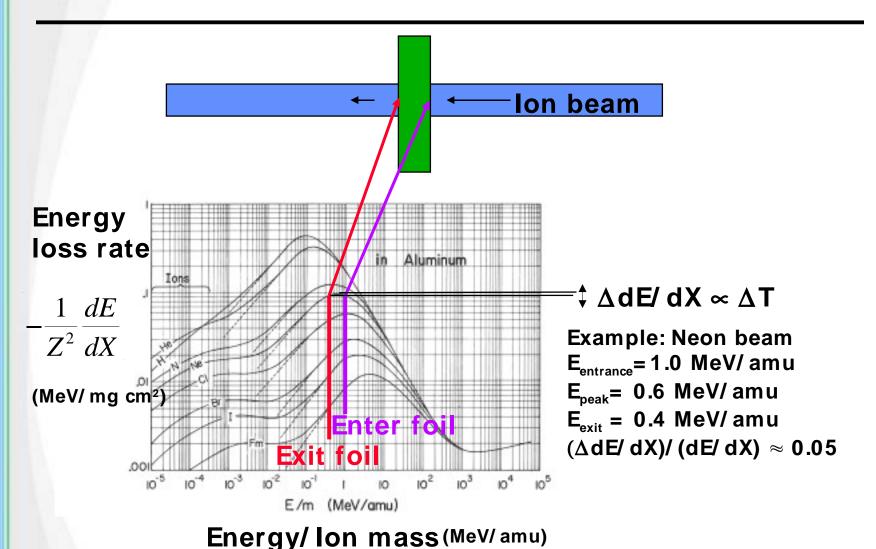

Warm dense matter research can help answer important questions about EOS

- Warm dense matter spans a regime that will help researchers distinguish between competing EOS models, but this requires accuracy (experiment or simulation) of a few percent
- The Hydra code is a well-benchmarked hydro code, but needs improved ion stopping to model ion driven WDM to the percent level

Ion beams can drive macroscopic targets to uniform temperatures for studying WDM states

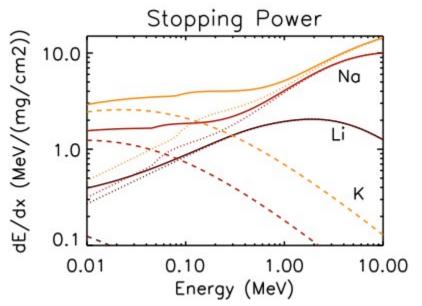

Tech- X Corporation

Tech-X and LBNL/LLNL collaborators are developing ion stopping models for WDM studies with the Hydra code

- Hydra will use TxPhysics, the new Tech-X algorithms
- Nuclear stopping in TxPhysics is an important new addition not presently available in Hydra

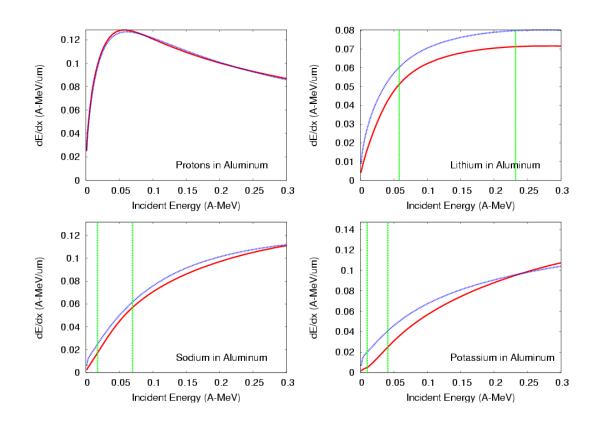

Dashed lines are nuclear stopping, dotted lines are electronic stopping, solid lines are total

Tech- X Corporation

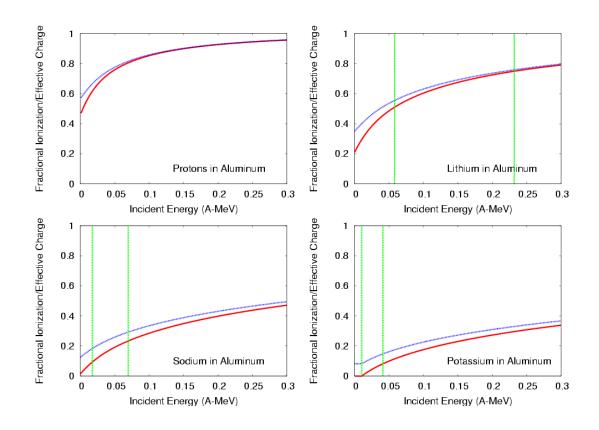

SRIM and TxPhysics give the same result to within 10% for ions/targets relevant to WDM

- Red is TxPhysics, blue is SRIM
- •Green lines are 400 keV and 1.6 MeV (relevant to NDCX II)

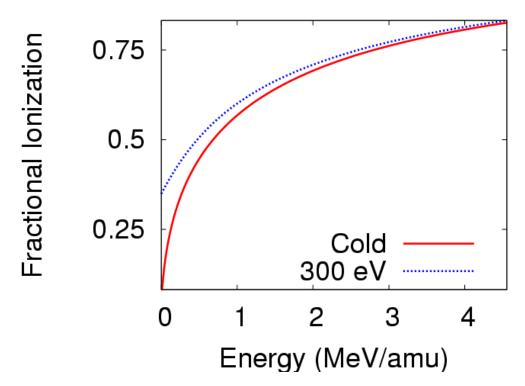

With TxPhysics, user has access to ionization state, effective charge, etc, if needed

- •Red is effective charge, blue is ionization state
- •Green lines are 400 keV and 1.6 MeV

We have also implemented modifications for warm stopping based on Mehlhorn*

Projectile ionization as a function of velocity in a cold aluminum target (red) and a warm target (blue)

Inertial Confinement Fusion Targets. J. Appl. Phys. 52, 6522

MEHLHORN, T. (1981). A Finite Temperature Model For Ion Energy Deposition in Ion Driven

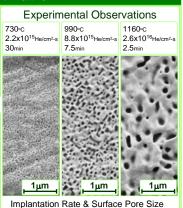

Simulation of Tungsten Surface Pores Formed by Low-Energy Helium Implantation

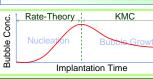

Akiyuki Takahashi¹, Shahram Sharafat², J. Kulcinski³ and R. Radel³, and Nasr Ghoniem²

¹Tokyo University of Science, ²University of California Los Angeles, ³University of Wisconsin at Madison

1. Motivation

- •Compelling experimental evidence: Low energy He ions implanted in W 730cc
- →unusual formation of oversized surface pores.
- •The High Average Power Laser (HAPL) project is developing an IFE power with W-armored FW.
- Explain <u>UW-Madison IEC facility</u>,
 Low-E He implantation in W.
- •Traditional *Rate-Theory* models are not suitable to simulate surface pore formation.
- New approach: Combine KMC techniques with Rate-Theory nucleation models.
- The new code: <u>MCMC</u>, which stands for <u>Monte Carlo simulation</u> of <u>Migration and Coalescence</u>.

2. KMC Simulation Method

Possible events in the KMC simulation

1. He Implantation

$$v^{imp} = A \rho^{imp}$$
 A: Surface area, ρ^{imp} : Implantation rate (He/cm²-s)

2. He Bubble Diffusion

$$D_b = \left(\frac{3\Omega^{4/3}}{2\pi r_i^4}\right) D_0 \exp\left(-\frac{E_s}{kT}\right) \frac{G}{E_s}$$

- Ω : Atomic volume, r_i : Bubble radius D_0 : Surface diffusion coe. $(10^{13}\delta^2/4 \text{/s})$
- E_s : Activation energy for surface diffusion(0.92 eV 2.5 eV)

3. He Bubble Coalescence

The bubble is immediately equilibrated

The bubble radius is determined by the equation of state.

4. Surface Pore Formation

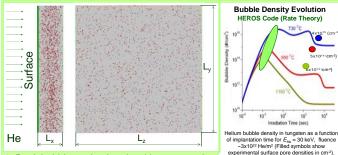

Note: He bubble nucleation saturates before M&C

3. Simulation Conditions

- Peak bubble nucleation densities are used as initial condition (taken from HEROS)
- 2. All He bubble diameters are initially same
- 3. The positions of He bubbles are given by a Gaussian distribution in the thickness (x) direction

	Temperature	Implantation Rate	L _x	L_y	L_z
	(°C)	(He/cm ² -s)	(µm)	(µm)	(µm)
Model-1	730	2.2x10 ¹⁵	0.2	1.0	1.0
Model-2	990	8.8x10 ¹⁵	0.2	2.5	2.5
Model-3	1160	2.6x10 ¹⁶	0.2	5.0	5.0

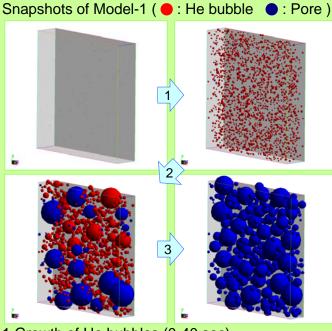

5. Comparison with Experimental Results

CONCLUSIONS

- •Good Agreement between RT-KMC Simulation and Experiment
- •Low Temperature Simulation Results are Lower than Data because T<0.3 T_m
 •<u>MCMC</u> Code provides an <u>EXPLANATION</u> for the oversized Surface Pores •<u>MCMC</u> Code development is continuing: <u>Pore THREADING</u>

4. Evolution of He Bubbles and Pores

- 1.Growth of He bubbles (0-40 sec)
- 2. Surface pore formations (40-160 sec)
- 3. Only surface pores (160-1800 sec)

High Velocity Dense Plasma Jets for MTF

F. Douglas Witherspoon, Andrew Case, Sarah J. Messer Michael W. Phillips, Richard Bomgardner, David van Doren

> HyperV Technologies Corp. 13935 Willard Road Chantilly, VA 20151 703-378-4882

High Velocity Dense Plasma Jets for MTF*

F. Douglas Witherspoon, Andrew Case, Sarah J. Messer, Michael W. Phillips, Richard Bomgardner. David van Doren *HyperV Technologies Corp., Chantilly, VA*

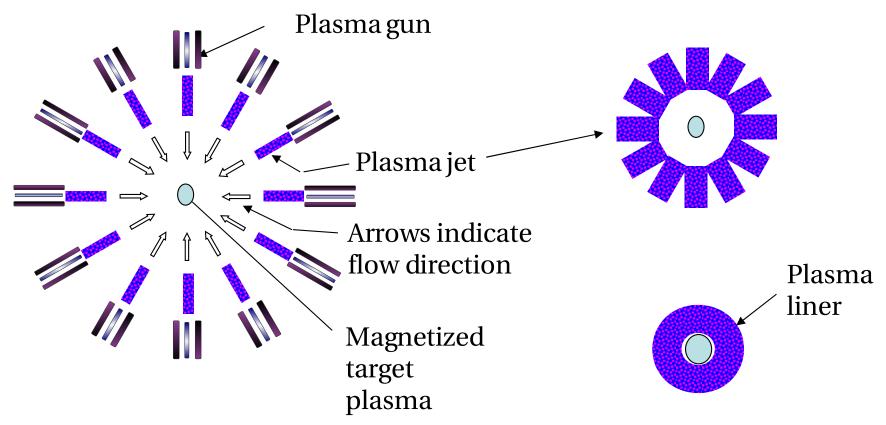

High velocity plasma jets are under development for a number of applications. The initial motivation for this line of research was Magneto-Inertial Fusion using high density, high velocity plasma jets as standoff drivers. Additional applications include reactor feuling, injection of angular momentum into centrifugally confined plasmas, HEDP, and others. The approach utilizes symmetrical pulsed injection of very high density plasma into the breech of a coaxial EM accelerator having a tailored cross-section geometry to prevent formation of the blow-by instability. Key to this approach is the mini-injectors used to produce the initial working plasma. We are following two parallel development paths to accomplish this initial injection. One uses a large number (ultimately up to 64) of electrothermal capillary discharges, while the second uses an even larger number of sparkgaps arranged in a toroidal configuration. Experiments are performed on two test fixtures; one is a 2pi configuration with 64 capillary injectors, and the second is a sparkgap array, which currently has 50 sparkgaps, but which is soon to be expanded to 112 in a new accelerator being fabricated using the sparkgap approach. Diagnostics used include Rogowski coils, Nikon D70s digital camera, a fast gated PI-Max camera, (which allows imaging of the plasma jets and their subsequent merging/interaction), and time resolved spectroscopy. Recent tests with a simple ballistic pendulum suggest the present half-scale prototype device is generating plasma jets with mass as high as 160 micrograms at 70 km/s.

^{*}Research funded by the DOE Office of Fusion Energy Science through Grants DE-FG02-04ER83978, DE-FG02-05ER54810, DE-FG02-05ER84189

Plasma Liner Driven HEDLP and MIF

- Plasma liner provides an avenue for solving three major issues
 - Standoff delivery of imploding momentum
 - Repetitive operation
 - Liner fabrication and cost
- It is capable of faster compression if faster compression is desired
- It can form strongly coupled plasmas
- Remote current drive by lasers or particle beams is possible
- Diagnostics opportunities: Provide clear view of both the liner and the target, thus enhances the diagnostics access

Merging of high Mach number plasma (dusty plasma) jets to form plasma (microns) liners

- An approximately spherical distribution of jets are launched towards a common center
- The jets merge to form a spheroidal shell (liner), imploding towards the center

TECHNICAL OBJECTIVE

Develop high density, high velocity plasma jets with:

$$> 200 \ km/s$$
 $> 100 \ \mu g$ $10^{16} - 10^{17} \ cm^{-3}$ $> Mach \ 10$

TECHNICAL APPROACH

Refine Coaxial Plasma Accelerator Basic technology requires refinement and modification to provide additional controls over plasma macrodynamics.

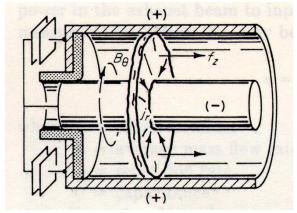

Tailored Electrode Profiles To suppress blowby instability

High Density Electrothermal Plasma Injection using pulsed capillary discharges.

- Injection velocities of 10-20 km/s readily attainable
- Densities of 10^{19} cm^{-3} in capillary possible
- High degree of annular symmetry using large number of small pulsed jets
- Capillary discharge technology is relatively robust

Extensive Diagnostics and Computational Modeling

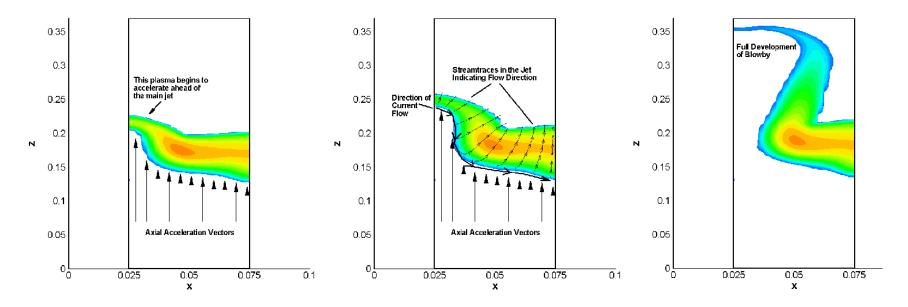

The Blowby Instability Limits Performance of a Classical Straight Coaxial Accelerator

*From R.G. Jahn, "Physics of Electric Propulsion," 1st ed., New York, McGraw-Hill, 1968.

The classical straight coaxial accelerator* can attain the velocity needed (i.e. 200 km/s) but has difficulty accelerating all the mass due to occurrence of the blow-by instability which can bypass much of the plasma mass.

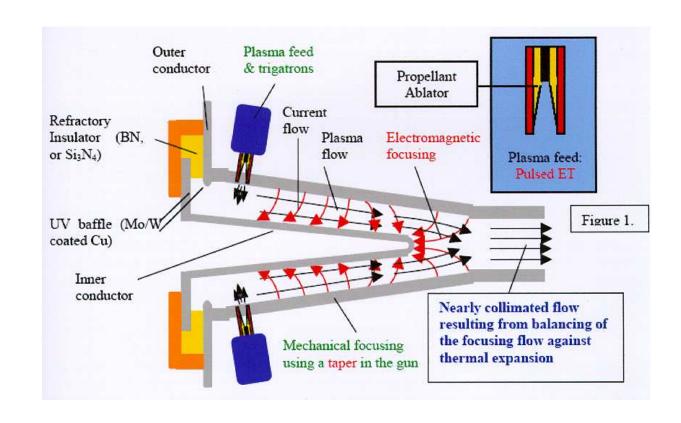

- B = 1/r
- higher $\overrightarrow{j} \times \overrightarrow{B}$ near inner electrode
- current distribution "runs away" leaving mass behind
- need to peak density profile near inner electrode

Mass density contour plots illustrate the blow-by instability in a straight coaxial accelerator. From Cassibry's PhD Dissertation referenced below.

Thio Suggested A New Methodology*

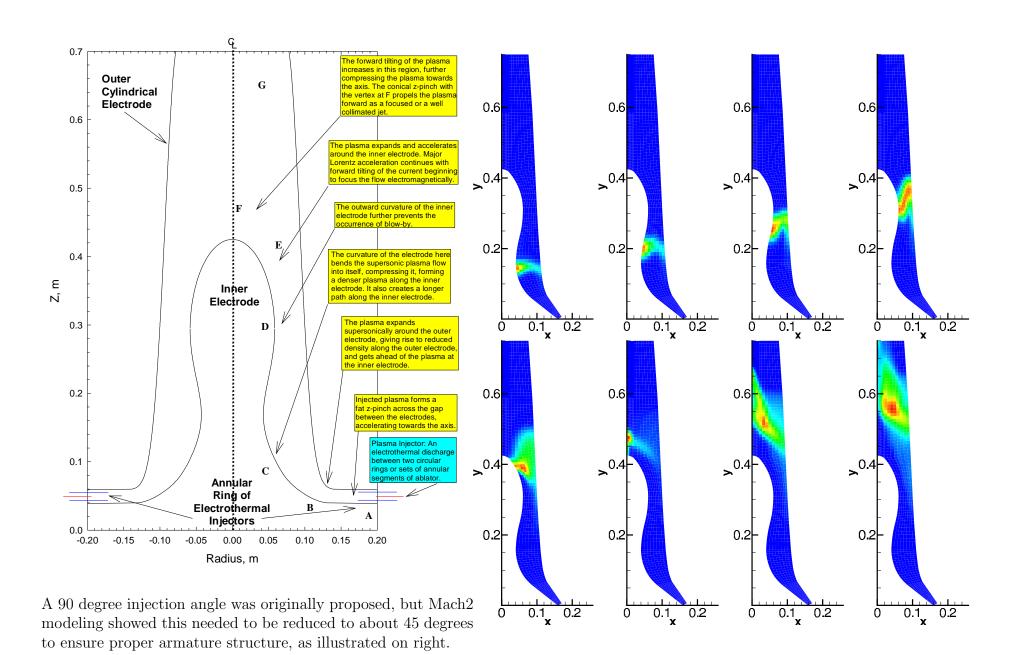

- No prefill is used. Operate at high vacuum. Any plasma to be accelerated is to be injected impulsively and nearly fully ionized with an initially high electrical conductivity. Electrothermal discharges were good possibilities.
- The main body of the plasma is sufficiently collisional so that the plasma behaves more like a fluid, to suppress the rich but undesirable particle kinetic effects.
- Taper the coaxial electrodes to provide some degree of macrodynamic control.

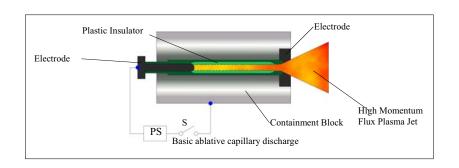

Cassibry and Thio also investigated exponentially tapered electrode profiles with encouraging results.**

Electrode Profile Tailoring Promises Greater Control of Plasma Macrodynamics

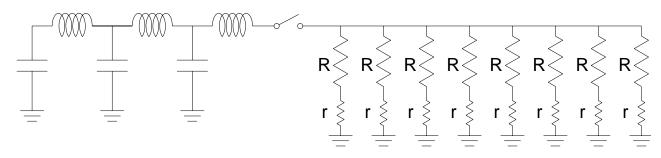

Plasma Injection is Accomplished Using Pulsed Electrothermal Capillary Discharges

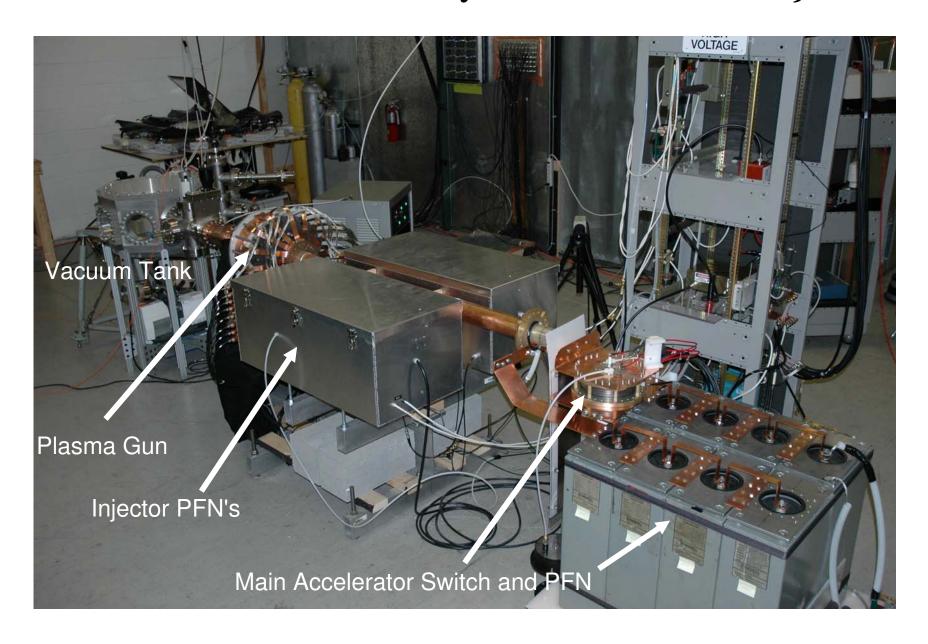

A capillary discharge can ablate large quantities of material off the wall, while controllably generating pressures up to several kilobars and temperatures of many eV. The exiting plasma jet can easily attain 10-30 km/s in vacuum.

A typical circuit for a single capillary discharge.

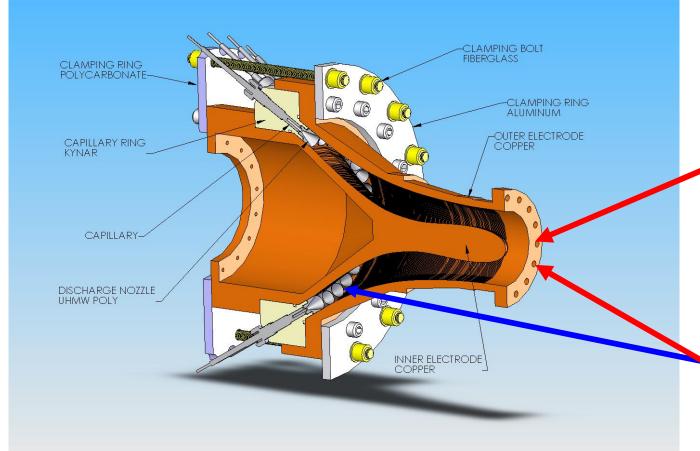

Driving capillaries in parallel requires large ballast resistance R in series with each capillary resistance r to ensure all capillaries will break down and then share current equally and stably.

Plasma Jet Accelerator System for MCX Injection

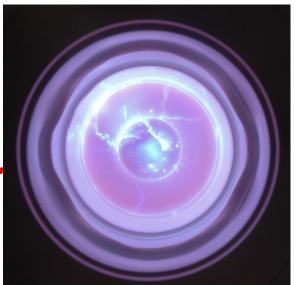

Plasma Jet Internal Structure

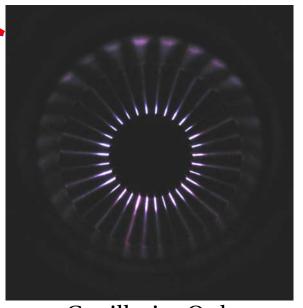

Visible Light

Cross-section of shaped main electrodes with 32 capillary discharge injectors.

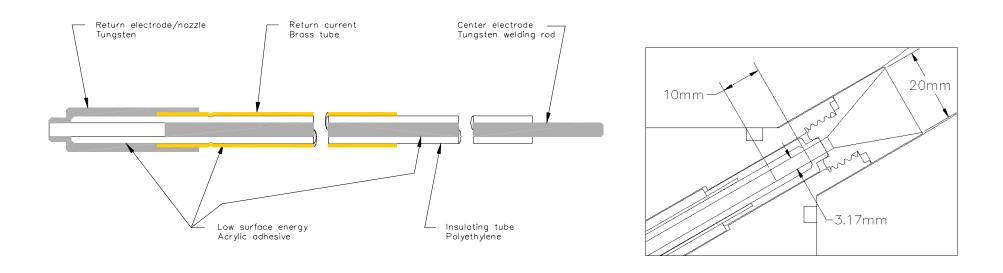

Main Current Pulse

Capillaries Only

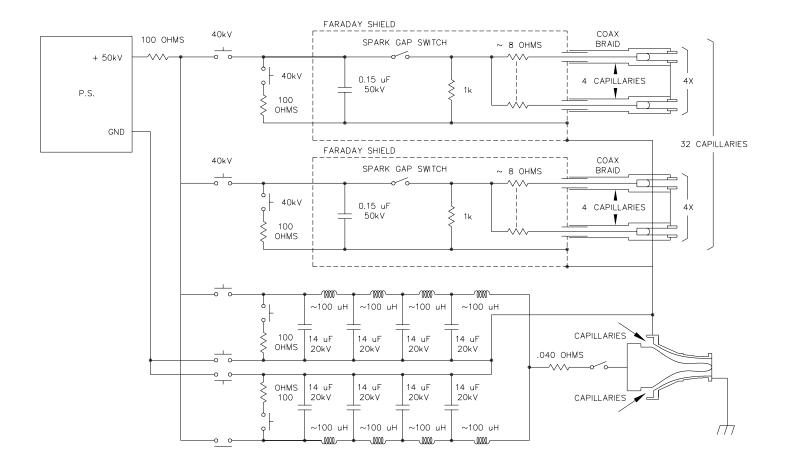

Photos are end view time integrated exposures.

Capillary Discharge Units in the Main Gun

Detailed view of internal structure of capillary used in main accelerator. Except for the tungsten nozzle which requires machining, all components are commerical-off-the-shelf items simply cut to length. Internal vacuum seals are achieved using acrylic adhesives. Mounting details are shown on right.

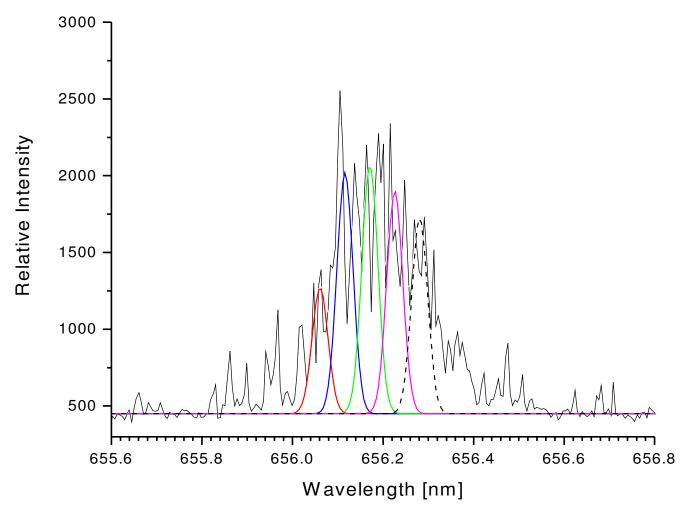

HV Accelerator Circuit

The High Voltage circuit for the capillary injectors utilizes two Titan 40624 sparkgap switches to drive 32 capillary discharges. Each switch drives four 0.15 μF Maxwell capacitors, each of which drives 4 capillaries in parallel with 8 ohms ballast in series with each capillary. The main electrode pfn has recently been upgraded as shown with eight 14 μF , 20 kV Maxwell capacitors arranged in two parallel legs. A 250 kA, 30 kV Beverly Associates spark gap switch Model SG-172C is used to switch voltage onto the rails after a typical 3 μs delay after the capillaries fire. This allows operation at higher voltages than previously attained with hot electrodes.

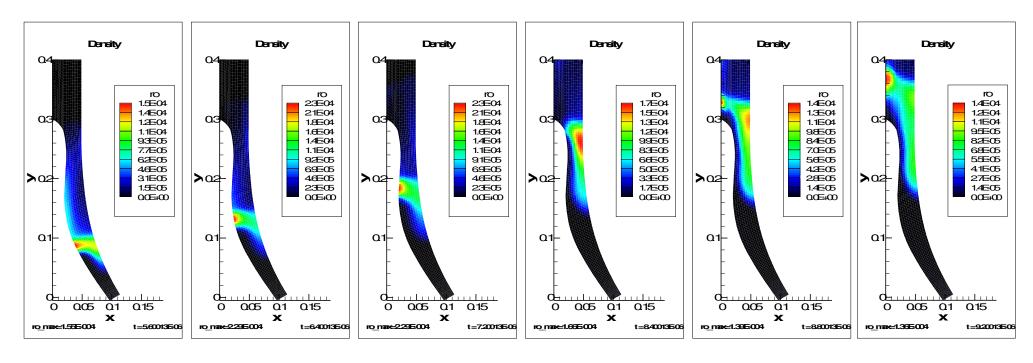

Gaussian Fits to Spectroscopy Doppler Data

Velocity Range is 50 - 100 km/s

Five Gaussian fit to Doppler shifted H_{α} line. Fit is obtained by convolving the Gaussians with the known instrumental line profile to obtain a best fit to the data. The Gaussians are centered at wavelengths corresponding to (from right to left) 0 km/s, 24 km/s, 50 km/s, 75 km/s, and 100 km/s.

HyperV Plasma Jet – Mach2 Simulations

Momentum and velocity follow rail gun scaling

Case above:

Mass = 87 gm

 $v_i = 5 \text{ km/sec}$

 $T_i = 5 \text{ eV}$

 $I_{\text{max}} = 187 \text{ kA}$

 $v_f = 88 \text{ km/sec}$

 $T_{r} = 131 \text{ eV}$

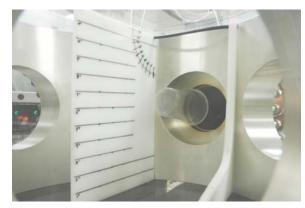

Momentum ~ I²

Exit velocity is mass dependent

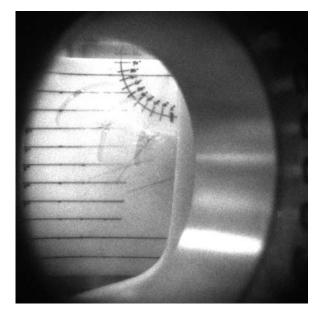

Ballistic Pendulum Tests

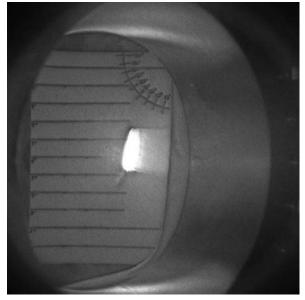

View of ballistic pendulum from angled port in vacuum tank.

The ballistic pendulum is constructed from a polyethylene support stand, using 100 micron tungsten wire, and 3 plastic drinking cups nested inside each other to obtain sufficient mass.

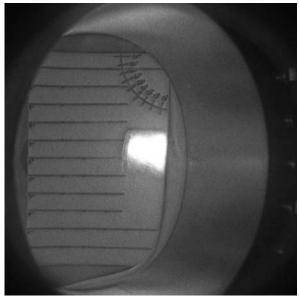

- Total combined cup mass = 12.75 gm
- Recoil velocity $\simeq 0.86 \text{ m/s}$
- Plasma velocity from Doppler shift $\simeq 70 \text{ km/s}$
- Calculated plasma mass $\simeq 157~\mu g$

(a) Multi-gate exposure using PI-Max camera. 25 ms delay from main trigger. Five gates at 100 ms apart, 8 μs exposure.

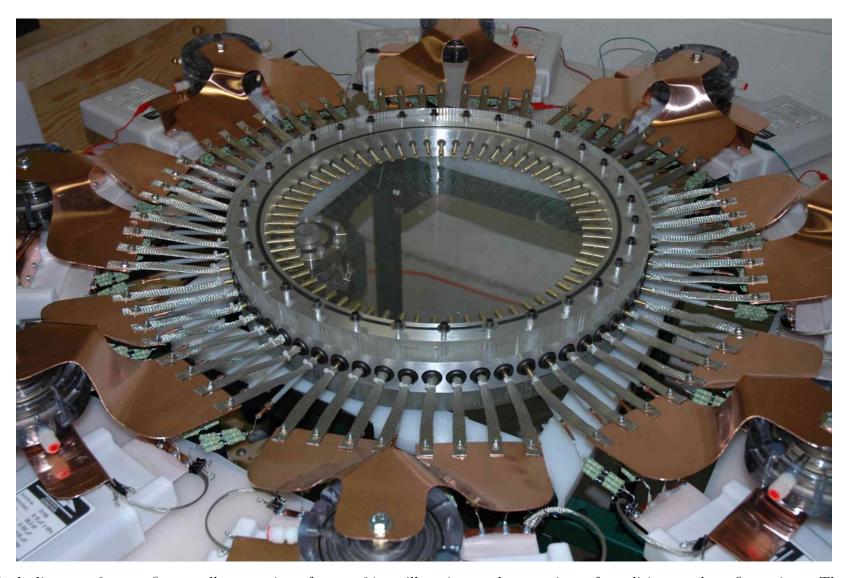

(b) Plasma stagnating on bottom inside of cup. From a PI-Max 50 ns exposure 18.5 μs after main trigger.

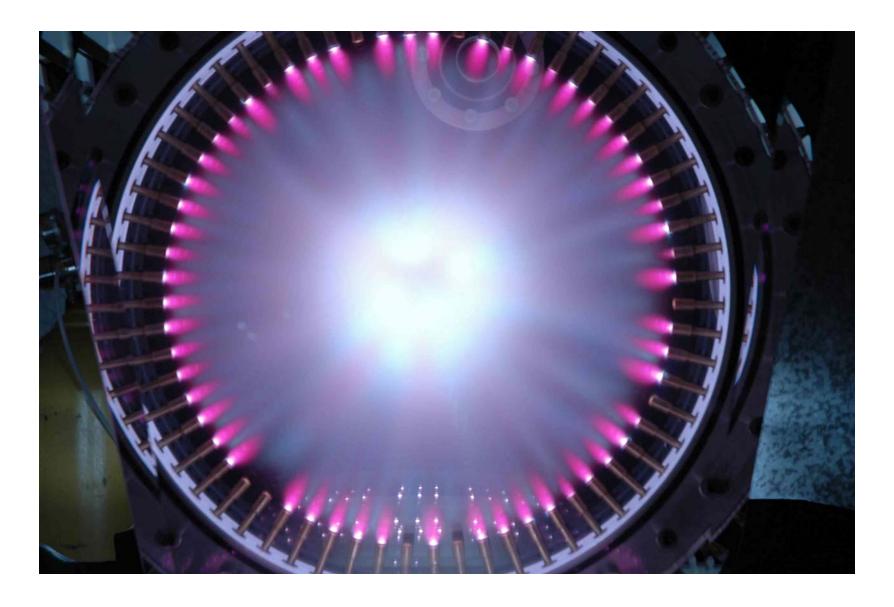

(c) Plasma expanding back to the right after impact at $28.5\mu s$ after main trigger.

The TwoPi Injector Test Fixture

The 24 inch diameter 2π test fixture allows testing of up to 64 capillary jets under a variety of conditions and configurations. The vacuum chamber operates at 0.7 mTorr using a 70 l/s turbopump despite the large number of seals. This photo shows the recently upgraded system with simple RLC HV circuit using a 0.15 μF Maxwell capacitor for every 4 injector units operating in parallel. A ballast resistance of about 1.3 ohms is in series with each capillary providing a (usually) stable and equal distribution of current at charge voltages up to 38 kV. Breakdown reliability suffers below about 28 kV.

Symmetric Jet Merging in the TwoPi Fixture

Implosion of almost 64 plasma injector jets. Diameter of aluminum vacuum chamber is about 24 inches.

Ion Implantation Effects on CVD SiC and Carbon-Carbon Velvet

Fusion Technology Institute, University of Wisconsin-Madison

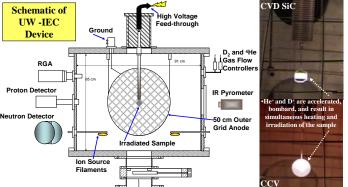

S.J. Zenobia, G.L. Kulcinski, R.F. Radel, R.P. Ashley, D.R. Boris

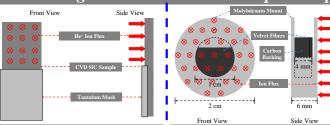

Materials Irradiation Experiments and the UW-Madison IEC Device

Summary of Presented Experiments

- SRIM calculations have been used to estimate the range of He⁺ in CVD silicon carbide (SiC) as well as the range of He+ and D+ in carbon-carbon velvet (CCV) and tungsten coated carbon-carbon velvet (CCV/W).
- CVD SiC samples (supplied by ORNL) were irradiated in the UW IEC device to 1x1018 and 1x1019 He+/cm2 at 850 and 950 °C.
- A partially masked SiC sample was irradiated to ~1.5x10¹⁹ He⁺/cm² at 950 °C
- CCV and CCV/W samples were irradiated to 1x1019 He+/cm2 at 1150°C and a CCV sample was irradiated to 1x1019 D+/cm2
- SEM analysis has been performed to evaluate the surface damage on the CVD SiC, CCV, and CCV/W as functions of temperature and/or fluence.

SRIM Range Calculations and Sample Setup

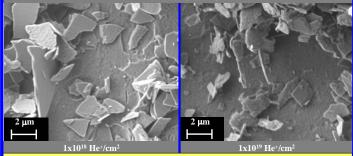

matic for masked CVD SiC

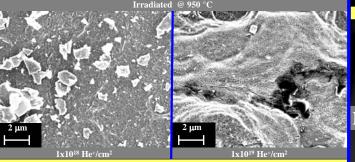

Projected Range of Implanted Ions Ion Energy (keV)

- To the left, ion ranges in CVD SiC, CCV and CCV/W are shown as a function of the IEC ion energy. Investigated implantation energies are noted
- ·Helium ion range in the CVD SiC corresponds roughly to the flake thickness resultant from irradiation (a few microns).
- None of the calculated ion ranges correspond to the damage penetration depth observed in the velvet specimens.

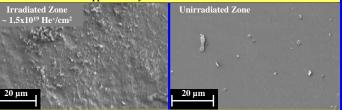

He⁺ Irradiation of CVD SiC

At 950 °C we notice flaking and pore formation in the 1x10¹⁸ He⁺/cm² sample and an increased level of pore formation in the sample irradiated to 1x1019 He+/cm2

Once again excessive flaking is evident on both specimens, though the level of pore ormation is not as high as the 1x10¹⁹ He⁺/cm² and 950 °C specimen. These flakes appear to be approximately several microns in thickness.

Lack of damage in the unirradiated zone confirms that the damage is due to helium ion fluence. The particles in the unirradiated zone are most likely a post-irradiation artifact

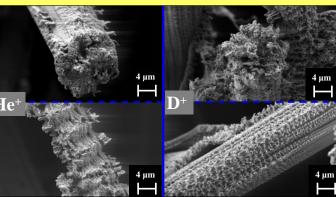

SiC Conclusions

- Significant changes in SiC surface morphology occur at both 850 and 950 °C and fluences (1x10¹⁸ He⁺/cm² to 1x10¹⁹ He⁺/cm²)
- At constant He⁺ fluence, the characteristic damage of the sample is a function of the temperature at which the sample is irradiated
- However, ion fluence NOT temperature, causes these surface morphology changes

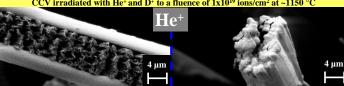

The authors gratefully acknowledge the financial support of the HAPL program at the Naval Research Laboratory

He⁺ and D⁺ Irradiation of CCV and CCV/W

Unirradiated Carbon-Carbon Velvet Specimen

CCV irradiated with He+ and D+ to a fluence of 1x1019 ions/cm2 at ~1150 °C

Tungsten-coated carbon-carbon velvet (CCV/W) irradiated with He⁺ to a fluence of 1x10¹ ions/cm2 at ~1150 °C

CCV and CCV/W Conclusions

- Both He+ and D+ irradiation of carbon-carbon velvet specimens cause fiber shaft corrugation, though He+ irradiated samples have a more pronounced
- Both He⁺ and D⁺ irradiation of carbon-carbon velvet specimens causes fiber shaft corrugation, though He+ irradiated samples have a more pronounced
- Some W-coated carbon fiber shafts incur rupturing, in addition to increased W surface roughness after He+ irradiation
